INDEX.

INDEX A.—Authors, Subjects, and Titles of Articles.

(Separate Indexes of "Book Review," "Miscellaneous," "Personals," "New Inventions," and "Trade Notices" follow the general index of articles.)

	Page.		Page.		Page.	
ACETYLENE GAS FOR MINE ILLUMINATION		Bituminous Mine Inspectors	554	Cars, Welsh Mine	198	
Accidents—In Coal Mines, 58; In Mines, 334.	406	Bituminous Mines, Increase in	400	Catlett, Charles	255	
Adams, Alton D.	160	Bituminous Statistics of Pennsylvania, 1900	508	Cave Ore Deposits	333	
Adams, Thomas K.	53	Black Sand	488	Caves, The Bat Guano	440	
Address of Welcome to the Western Pennsylvania Central Mining Institute at Johnstown, Pa.	556	Blue, Archibald	181	Cement Flumes	219	
Ald Packet, First	207	Blueprints, Waterproof	493	Central Station, A Rat Shutting Down a	101	
Air Crossings or Air Bridges	285	Board of Examiners for Mine Inspectors, Etc. (Pennsylvania)	401	Centrifugal Ventilators	28, 118	
Air Locomotives, Compressed	188	Boilers, Care of	106	Cerrillos Anthracite Mine	341	
Air Needed for Ventilation, Quantity of	89	Boiler Compounds, Soda Salts as	129	Change of Ore Bodies with Change of Country		
Air Shaft, Ventilating	69	Boiler, Horsepower of	22	Rock	417	
Airways, Size and Shape	185	Boilers, Prevention and Removal of Scale in Water-Tube, and Forced Draft	33	Changes in Anthracite Coal	258	
Alabama—Coal Production, 161; Coal Fields, 446; Ensley, 220; Mining Methods, 195; Warrior Coal Basin, 268.		With Too Much Heating Surface	8	Changes Steel May Undergo in Tempering	43	
Alamo District, Lower California, Mexico	507	Book Reviews	26	Charcoal, By-Products from	542	
Alaska—Dawson and the Yukon Territory, 55; Gold Mining in, 438.		20, 68, 116, 164, 212, 260, 308, 355, 404, 451, (See Index "B" for list of books reviewed)	500	Chibias, Eduardo J.	295	
Alderson, Matt. W.	322	Boot for Mining Men	501	Chicago-Schnucker Rock Drill	860	
Alexander Car Replacer	213	Bore Holes (Draining Gas From Gob Workings)	61	Chicago, Wilmington & Vermilion Coal Co.	145	
Allen, Wyatt H.	421	Boring Machine Adapted for Boring Against Wastes	416	China, Prospecting in	393	
Allied Cyanide Companies of America	213	Boundary District, B. C.	342	China, The Tong Colliery	320	
Aluminum, New Uses for	405	Bowden, J. H.	177	Chlorination, Cyanidation vs.	842	
American and Welsh Coal	554	Bowie, A. J.	529	Chlorination Mills	837	
American Nettle Mine	241	Box-Car Loading	152	Chlorination Process	108	
American Steel and Wire Co. Acquires Vessels	251	Brackenbury, Cyril	150	Claims, Locating Mineral	69	
American Steel and Wire Co., At the Paris Exposition	272	Breckenridge, Colo.	222	Clarke, W. B.	389, 555	
Andesites	125	Brennen, J. P.	385	Clark, W. C.	101, 343	
Anthracite Coal Changes	258	Brinsmade, R. B.	103, 155, 363	Clays Associated with Coal Seams	331	
Anthracite Mines—The Cerrillos	341	British Columbia (Gold Dredging)	9	Clearance	449	
Anthracite, Preparation of	70	British Columbia Boundary District	214, 342	Coal—Accidents in Coal Mines, 58; Alabama Coal Fields, 446; Alabama Production, 161; American and Welsh Coal, 554; Anthracite Mines, The Cerrillos, 341; Appanoose County Coal Field, 845; Brown Coal in North Dakota, 545; Brushy Mountain Mines, 438; Clays Associated with Coal Seams, 331; Coal Carrier, Bartlett, 286; Coal and Metal Miners' Pocket-book, 260, 355, 401; Coal and Mines of South Wales, 459; Coal Creek, Tennessee, 391; Consumption of, in France, 109; Curtis Mine, 298; Dangerous Roof or "Top" in Coal Mining, 381; Fields and Seaports, 534; Illinois Coal Operators, 251; In India, 57; In Rhodesia, 367; Iowa Mining Methods, 126; Mined by Machines in 1899, 187; Mining in New South Wales, 290; Missouri Coal Statistics for Year Ending June 30th, 1900, 414; New Mexico, New Coal Field, 375; Norton Mines, 299; Outcrops, 255; Philippines, Coal Fields of, 205; Pictou Mines, 1; Production of, by states, 190; Streater, Mines at, 145; Strength of, 19; United States Statistics, 114; Used in St. Louis, Mo., 267; Value of Coal Lands, 28; Vancouver Island Mining, 249; Vancouver Mines, 589; Warrior Coal Basin, 268; World's Product of, 195.		
Antidote for Lead Poison	260	British Columbia, Mineral Production of	466	Coal Mining in Belgium	558	
Antimony	319	British Columbia, Mining in	60, 368	Coal Mining Under Sydney Harbor, New South Wales	557	
Appanoose County Coal Field	345	British Columbia Mining News	553	Coeur d'Alene District, Idaho	23	
Arbitration, Conciliation and	306	British Columbia, Nanaimo, Examinations	569	Coeur d'Alene, Tunnel Developments at	101	
Argo or Newhouse Tunnel	81	British Gulana, Diamonds in	141	Coke—Larries, Electrically Operated, 46; Ovens, Welsh, 11; Plant, Eureka Fuel Co., 385, Coking Plant, 49.		
Arizona—Copper Deposits of 12; Mines and Mining in Yavapai County 46; Notes 71, 117, 358.		Brown Coal in North Dakota	545	Colliery Guardian	476	
Aragon Mine	494	Brown, Walter	382	Colorado, 1, 81, 147, 224, 241, 276, 291, 298, 333, 337, 399, 481; Colorado vs. Switzerland, 17; Breckenridge, 222; Fairplay near Alma, 128; Colorado Fuel & Iron Co. (Coal Mines of Pictou), 1; Mining in, 415; Oils and Oils, 67.		
Arrangement of Shaft Bottom	406, 454	Brushy Mountain Coal Mines	438			
Arsenic, Sulphide of	69	Buffalo Hump, Idaho	296			
Ashton Co.'s Paris Exhibit	868	Bunnell Rock and Ore Crusher	449			
Ashworth, James	490	Burning Mine at Summit Hill	497			
Assay Office, The Seattle	245	Burt Exhaust Head	24			
Atlas Pipe Wrench	368	Business Proposition	560			
Auchmuty, H. L.	484	Butte, Mont.	103, 155, 423			
Australia, Competition with American Kerosene in	178	By-Products from Charcoal	542			
Automatic Injector	221					
Automatic Lubricator	16					
BALANCED SHAKING SCREEN.		CABLES				
Bartlett Coal Carrier	113	Cable, Test of Flattened Strand	489			
Basalts and Basaltic Lavas	286	Calculations Pertaining to Pumps	537			
Bat Guano Caves	228	Caldwell, Prof. F. C.	328			
Beard, J. T.	126, 371, 440	Calkins' Gyratory Muller	436			
Belgium, Mining in	524	Calendar, A Unique	526			
Bell, R. N.	568	California, Oil Fields of	376			
Belts, Driving Power of	174	Canada, Ontario Mine Law	467			
Berwind-White Coal Mining Co.	312	Canadian Iron Ore	181			
Best Arrangement for an Escapeway	110	Cannel Coal	259			
Biggart, Andrew S.	406	Canton Duplex Mine Pump	505			
Birkenhead, Lapidary Industry of	371	Capacity of Exhaust Pipe	253			
	81	Capital and Labor, Relations of	406			
		Carbon County, Mont.	496			
		Care of Boilers	214			
		Care of Maps	109			
		Car Loading, Box	159			
		Cars, Handling	152			
		Cars, Star Mine	547			
			200

INDEX.

v

Page.		Page.		Page.
401	Examiners, Board of	254	L ABOR AND CAPITAL, RELATIONS OF	496
84	Example of the Granite Series in the Field	108	Lake Copper Industry	397
113	Excellent Work on Pumps	517	Lake Ore Matters	60
219	Exeter Noiseless Gravity Conveyor	310	Lakes, Arthur	12, 81, 55, 108,
24	Exhaust Head, Burt	287	112, 128, 140, 147, 204, 222, 224, 241, 276, 291, 298,	
179	Exhibit, The Paris, of the Ingersoll-Sergeant Drill Co.	355	333, 337, 341, 375, 395, 417, 430, 443, 467, 477, 481,	509
307	Exit D. V. & K. R. R.	545	Lake Superior Copper Mines	78
112	Experimental Ore-Testing Works		Lake Superior Copper Mining	158
128	Exploiting a New Placer Field		Lake Superior Iron Trade During 1900	318
499	Export Exposition, Floating		Lands, Value of Coal	23
			Langwith Colliery	892
			Lapidary Industry of Birkenfeld	81
			Larries, Electrically Operated Coke	46
			Lattimore Mfg. Co.	123
			Lattimore's Patent, Decisions Sustaining	123
			Lavas, Basaltic	228
			Law of Ontario, The Mines	131
			Leaching Copper Ore	262
			Lead, and Fluorspar District, Kentucky Zinc	71
			Lead Poisoning, Antidote for	260
			Leadville, Colo.	147
			Leaks, Prevention of	8
			Lee, Harry A.	415
			Legislature of Montana	507
			L'Hame, Wm. E.	558
			Liberty Bell Mine	399
			Light in Mines and Factories, The Use of	201
			Lignite Deposits	545
			Limonite Ores of Pennsylvania	97
			Litchfield Hoisting Engines	462
			Little Things, System and Attention to the	8
			Llano Mineral Field	262
			Loading, Box-Car	152
			Locating Mineral Claims	69
			Location of Mineral Claims on Railroad Lands	166
			Locomotive, Compressed Air	188
			Locomotives, Electric	226
			Locomotive, Electric Mine	208
			Locomotives, Mine	555
			London Fault, The Great	204
			Longwall Mining Machine, The Jeffrey	396
			Longwall Undercutting Machines	82
			Lower California, Alamo District	507
			Low-Water Alarm	313
			Lubrication	329
			Lubricator, Automatic	16
			Lumber Rafts, Ocean	180
			Lunkenheimer Automatic Injector	221
			Lunkenheimer '99 Model Standard Injector	525
			Lyon, D. A.	245, 349
			M CALLISTER, A. S.	110
			McCalley, Henry	263, 446
			McFarland, Walter M.	3
			McGregor, Alexander	560
			Machinery, Standard Mine	211
			Machine Mining in Illinois	214
			Machine Shop, A Modern	245
			Machines, Rib Drawing With	82
			Madison Coal Co.	462
			Magenau, William	299
			Magnetic Iron to Copper Ores, Relation of	22
			Maguire, Don	4, 275, 388, 504
			Manganese Mining in Cuba	295
			Manometrical Efficiency	524
			Manufacture, Economy in	85
			Maps, Care of	159
			Maps, Making of Mine	301
			Mark Twain on Mines	511
			Marquette Mines, Pere	100
			Martin, Claude V.	801
			Martin, Robert	416
			Mason, Frank H.	141, 542
			Mathez, Auguste	393
			Meade, Frank	1
			Mechanical Draft	165
			Mechanical Gold Washer	79
			Memorial Fountain, The Wolf	211
			Mensuration	69, 118
			M. E. or E. M.	810
			Meredith, Wynn	421
			Meridian of a Survey	233
			Mesabi Range	150
			Metallic Paint	495
			Metallurgical Features of the Paris Exposition, Some	273
			Metallurgy of Gold	311
			Metallurgy of Zinc	34, 58
			Metamorphic Rocks	323
			Method of Connecting Survey	484
			Method of Opening a Coal Seam	310
			Method of Opening and Ventilating a Mine	552
			Methods, Iowa Coal-Mining	126
			Methods of Shaft Timbering	133
			Metric System in Europe	488
			J ACKSON BELT-LACING MACHINE	280
			Jacobs, E.	466
			Jeffrey Air-Power Longwall Mining Machines	396
			Jeffrey Electric Power 45" Cut Shearing Machine	478
			Jessup, A. B.	493
			Jig Wheel and Brake	407
			Jockeys Used in Endless-Rope Haulage	357
			Justi, Herman	251, 496
			K ELLY & NEWHOUSE TUNNELS	509
			Kentucky Zinc, Lead, and Fluorspar District	71
			Keeping Timbering Plumb in an Inclined Shaft	552
			Kerosene Gas Engines	562
			Kerosene Engine	176
			Kerosene in Australia, Competition with American	173
			Klondike, Mining on the	529
			Klondike Region, New Coke Plant in the Pennsylvania	385
			Krupp Industries	272
			H ABETS, M. MARCEL	254
			Haile Gold Mines	55, 108
			Handling Cars	517
			Hardening Steel	310
			Hart, James	287
			Hartsfeld Scheme, A New	355
			Haseltine, R. M.	545
			Haulage, 44, 92, 340, 454, 505—Compressed-Air	
			Locomotive, 188; Cost of, in Great Britain,	
			332; Endless-Rope, 220, 454; Haulage Plant,	
			Compressed-Air, 177; Haulage Problem, 22,	
			263; Haulage Rope, 145; Rope Transmission	
			in Mine, 89.	
			Heating and Ventilating by the Blower System	517
			Heating Surface, Boilers With Too Much	26
			Heminway Process, Improved	412
			Hepplewhite Tapered Pit Props	302
			Hepplewhite, W. Hutton	302
			Herzig, C. S.	65, 344
			Herzler & Henninger Mining Machine	455
			Heworth Colliery	398
			History of Working Siberian Mines	123
			Hoepfner Electrolytic Process	321
			Hoisting Engineer's Examination	185, 380
			Hoisting Engines, Litchfield	462
			Home-Made Assay Furnace	357
			Hopkins, T. C.	97, 852
			Horsepower of a Boiler	22
			Howarth, O. H.	556
			Howe Culum and Sand Dryer	269
			Howell, Hon. A.	459
			How to Make Gold Dredging Pay	186
			Huist, Dr. Nelson P.	246
			Hydraulic Mining, Notes on	202
			Hydraulic Ram	552
			I DAHO, 401; A GLANCE BACKWARD, 57;	
			BUFFALO HUMP, 296; COEUR D'ALENE	
			DISTRICT, 23; DEEPEST MINE IN, 174.	
			Idaho, Thunder Mountain	558
			Igneous Rocks, Andesites	125
			Illinois—Examinations, 377, 379, 380; Illinois	
			Coal Operators, 251; La Salle County, 145.	
			Illuminating Oil for Mines	454
			Improved Heminway Process	412
			Inclined Seams, Roadways in	184
			Inclines, Transportation on	10
			Increase in Bituminous Mines	400
			Increasing Steam Engine Efficiency	141
			India, Coal in	57
			Indiana—Examination Question	825
			India Rubber	222
			Industries, Peru's Mining	80
			Industry in the Ural Mts., Mineral	40
			Industry of Birkenfeld, The Lapidary	81
			Injector, Automatic	221
			Injurious Effect of Clearance in an Air Com-	
			pressor	293

			Guano Caves, The Bat	440
			Gunpowder, as an Explosive in Coal Mining	218
			Gypsum or Plaster of Paris	166

	Page.		Page.		Page.		
Mexico, Lower California Alamo District, 507; Mines of Velardena, 51; The Cordillera of, 556.		Mining Wrinkles (Continued).		Outside or Inside Packed Pumps	214		
Mica	505	Mines, 237; Improved Rock-Drill Fastening, 237; Loose Tail-Rope System of Haulage, 141; Marking Roof Stations in Mine Surveying, 237; New Device for Reheating Compressed Air for Use in Pumps, 77; Sheaving on a Curve, 270; Water Car, 77; Water Filtration, 270.		Ovens, Welsh Coke	11		
Michigan—494; College of Mines, 116, 549; Nor- way, 494; Pere Marquette Mines, 100.		Minnesota (Messabi Range)	150	PACKET, FIRST-AID	207		
Mine-Car Hitchings	278	Miscellaneous Queries	117	Paint, Metallic	495		
Mine Cars, Star	200	Miscellaneous Questions	406	Pan-American Exposition	411		
Mine Cars, Welsh	198	Misfire Shots	357	P. & B. Products	83		
Mine Cross-Sections	161	Misfire Shots With Electric Battery	262	Paris Exposition	190, 347, 368		
Mine Discipline	487	Missouri	414	Paris Exposition, The Crane Co. at	238		
Mine Examiner's Examination, Illinois	879	Missouri, Zinc-Lead Regions of	559	Paris Exposition, Some Metallurgical Features of the	278		
Mine Fire at Butte	423	Mistaken Secrecy	307	Parker, E. W.	190, 208, 298, 420, 584		
Mine Foreman's Examination		Modern Machine Shop	245	Paris Exhibit	179		
..... 185, 181, 230, 325, 424,	471	Modulus of Elasticity of Wire Ropes	406	Paris Exhibit of the Jeffrey Mfg. Co.	229		
Mine in Idaho, Deepest	174	Monaghan, Consul	420	Paris Exposition	190, 272		
Mine Inspector's Examination	41, 86,	Montana	275, 322	Parker Shaft, Electric Signals at	419		
Mine Haulage, Rope Transmission	89	Montana, Butte	103, 155,	Patents (see New Inventions)			
Mine Locomotives	555	Monte Cristo District, Wash.	69	 47, 95, 143, 191, 289, 287, 335, 383, 431, 479,	527		
Mine Locomotive, Electric	208,	Morganroth, L. C.	8	Payne, Ernest E.	51		
Mine Machinery, Standard	211	Moss, Dr. R. S.	412	Pea Coal, Use of	269		
Mine Manager's Examination	377, 515,	Mustard Gold	362	Peculiar Geological Formations	430		
Mine Pumps	358	Myers, H. K.	183,	Peculiarities of Siberian Placers	201		
Mine Surveying Problems	559		226	Peculiar Mines and Ore Deposits	224		
Mineral Claims, Locating	69	NANAIMO, B. C. (EXAMINATION QUES- TIONS)	515,	Pennsylvania, 352, 354, 461, 508—Anthracite Sta- tistics, 461; Examination Questions, 183, 181; Glen Lyon, 177; Limonite Ores of, 97; Wind- ber, 110.	100		
Mineral Exhibits of the Pan-American Exposi- tion	411	Naphtha Safety Lamp With Magnetic Locking Device	351	Pere Marquette Mines	350		
Mineral Exports	450	Nettle Mine, The American	241	Persia, Mineral Resources of	238		
Mineral Industry in the Ural Mountains	40	Nettleton, F. C.	418	Personals			
Mineral Paints	515	Nevada	299,	 24, 27, 68, 116, 169, 218, 261, 305, 356, 401, 453,	501		
Mineral Production of B. C.	466	New Coal Field	375	Peru's Mining Industries	80		
Mineral Production, The World's	162	New Coke Plant	385	Petroleum, 467, 540, 548—Oil Fields of California, 467; Origin of, 540.			
Mineral Resources of Persia	238	New Design for a Compound Duplex Pressure Pump	140	Philippines, Coal Fields of	205		
Mineral Resources, Siberia's	68	New Electric Sinking Pump	154	Phillips, William B.	440		
Miners' Inch, Standard	549	New Hartefeld Scheme	355	Phosphate Rock	225		
Mines, Accidents in	334	Newhouse Tunnel, Argo or	81	Pictou, Coal Mines of	1		
Mines, Accidents in Coal	53	New Inventions		Pipe Line for Steam	505		
Mines and Minerals, A Striking Endorsement for Mines and Minerals, Vol. XXI	403	 47, 95, 143, 191, 239, 287, 335, 383, 431, 479,	527	Pipe Wrench, Atlas	368		
Mines and Mining in Yavapai County, Arizona	46	New Mexico—Coal Mine, 341; New Coal Fields of, 375; Turquoise Mines of, 395.	466	Pit Props, Hepplewhite Tapered	302		
Mines and Ore Deposits, Peculiar	224	New Mine Fan		Pittsburg Rotating Gage Cock	382		
Mines at Streator, Coal	145	New South Wales, Coal Mining in, 290; Miners, The Rate of Wages Paid to, 298; Coal Mining Under Sydney Harbor, 557.	225	Placer Field, Exploiting a New	128		
Mines, Down Town	147	New Throttle Valve	405	Placer Mines of Washington	262		
Mines, Drainage and Pumping in	69	New Uses for Aluminum	142	Placer Mining Notes and Wrinkles, Some	140		
Mines, Electric Wiring in	160	New Water Purifying System	545	Placers, Peculiarities of Siberian	201		
Mine Service, Pumps for	283	New Zealand	102	Placers, The Genesis of Siberian	107		
Mines for Pennsylvania, A Department of	354	North Dakota, Brown Coal in	289	Planes, Gravity—Number of Cars Required	284		
Mines, Lake Superior Copper	78	Northern Wisconsin, Copper Mining in	102	Plant, Coking	49		
Mines Law of Ontario	181	Norton Coal Mines	289	Plant, Electric	110		
Mines, Mark Twain on	511	Norway, Michigan	494	Plant, The New Coke	385		
Mines, Norton Coal	289	Notes, Arizona	71	Pocket Slide Rule	161		
Mines of Pictou, Coal	1	Notes on Hydraulic Mining	202	Poisoning, Antidote for Lead	260		
Mines of Velardena, Mexico	51	OBITUARY, 78, 115, 165, 261, 353, 453, 502, 504, 541—Bedford, T. A., 353; Blakeslee, James I., 453; Bowden, James H., 209; Brooks, Thomas Benton, 261; Chambers, R. COAL MINES OF PICTOU.

A Description of the Mines of the Colorado Fuel & Iron Co., the Methods of Operation, and the Geological Formation.

Written for MINES AND MINERALS, by Frank Meade.

The coal mines of Pictou, Colorado, are located in Southern Colorado along the eastern border of the foothills of the Rocky Mountains, among the pifion hills. The camp is situated about midway between Pueblo and Trinidad on a spur of the Denver & Rio Grande Railroad, which takes out from Walsenburg, the county seat of Huerfano County, about two miles to the south, which is the nearest express office. The celebrated Spanish Peaks, about 20 miles to the south, have from time immemorial formed the principal landmarks in these parts.

The name "Pictou" was given to the camp at the time the mines were opened, some 12 years ago by its first superintendent, the late Thomas Lawther, he having formerly resided in Pictou, N. S. Its population will run from 1,000 to 1,500, being a mixed class of nearly all nations. Fine little cottages are built by the different companies for the accommodation of the miners, the C. F. & I. houses are four-roomed buildings; many, however, have built their own homes.

There are several companies operating mines here, the most prominent being the Colorado Fuel & Iron Co., with a capacity of 1,500 tons daily, employing, when at its full capacity, from 500 to 600 men, the Northern Coal Co., capacity 400 tons daily, employing about 150 men, the Victor Fuel Co., capacity about 500 tons daily, employing about 200 men, all of Denver, and several smaller companies.

All the mines are worked by slope openings, ventilated by upcast fans, equipped with cable haulage, landing the mine cars on trestleworks in order to get fall enough to screen the coal. The coal is dumped by Mitchell tipples over screens into the railroad cars.

The miner gets paid by the ton for what coal goes over the screens, and it is weighed in the railroad car, rods connecting the scales with the weigh house which is on top of the trestle.

The screenings are screened again, each company having a different process, the C. F. & I. produces two grades of nut coal (i. e., nut and pea) by a shaker screen run by a small electric motor, while the slack is shipped to the steel works of the company at Bessemer. The nut coal, before passing into the box cars, is discharged onto an endless apron, where boys pick the slate out as it passes along. All the different mines here are located on the same series of coal veins, which consists of three veins with a 5-per-cent. dip to the west of south.

As the Colorado Fuel & Iron Co.'s plant here is the oldest, largest, and most productive, and as the openings and workings of the different mines are practically the same, I shall confine my description to it.

This company is the only one working all three veins. (For section of workings see Fig. 1.) The top vein, No. 1, called the "Lenox" coal, consists of about 7 feet of coal mixed with more or less slate, i. e., a top coal of 1½ feet, a middle coal of 4 feet, with 6 inches of slate, between, and a bottom coal of 1½ feet with slate between it and the middle coal. The slate is gobbled in the rooms. One of the peculiarities of this vein is the 1½ feet of top coal, or perhaps rather the slate between it and the middle coal. As this coal is followed down on the dip the slate becomes thicker, until, in the bottom of the workings, this slate is 30 or 40 feet thick.

As long as this slate did not exceed 2 feet in thickness it was gobbled in the rooms, but as it becomes thicker it is kept up with timbers, the rooms worked out, and the pillars drawn, after which this slate often comes down, leaving the coal hanging. In such cases track is laid on top of this fall of slate, and this coal is taken out. It requires very little powder, and although a dangerous job, it is considered one of the snaps of the mine. Another characteristic of the No. 1 vein is that its dip is irregular as compared with Nos. 2 and 3, which are very continuous, as will be seen from Fig. 1.

Below No. 1 vein, through 32 feet of sandrock, lays No. 2 vein, the Maitland coal, it consisting of 4 feet of clean coal, with a fine sandrock roof. In most places in this mine the bottom has to be taken up in the roadways to make them high enough for the mules. Very little timbering is required in this vein.

Twelve feet underneath No. 2 vein, through slate rock, exceeds 2 feet in thickness it was gobbled in the rooms, but as it becomes thicker it is kept up with timbers, the rooms worked out, and the pillars drawn, after which this slate often comes down, leaving the coal hanging. In such cases track is laid on top of this fall of slate, and this coal is taken out. It requires very little powder, and although a dangerous job, it is considered one of the snaps of the mine. Another characteristic of the No. 1 vein is that its dip is irregular as compared with Nos. 2 and 3, which are very continuous, as will be seen from Fig. 1.

FIG. 1. SECTION AT COLORADO FUEL & IRON CO.'S MINE, PICTOU, COL.

sandrock and soapstone, respectively, comes No. 3 vein, the Cameron coal, the finest coal in Pictou, it being 5 feet 10 inches in thickness, of clear coal; the roof, however, is the poorest of the lot, taking a good deal of timbering, it being necessary in most places to cross-bar it.

Pictou coal is a semibituminous coal, and is known to the trade as a No. 1 steam coal. The analysis of Nos. 1 and 2, as given by Prof. Chauvenet, of the State School of Mines, at Golden,

Sulphur	1.39	2.04

Colorado, is shown in the accompanying table. I regret that I am unable to furnish analysis of No. 3 vein, but it is very similar to Nos. 1 and 2. The coals dip to the west of south with a 5-per-cent. pitch. A peculiar characteristic of this coal is the "nigger-head" form, like

boulders, which it frequently assumes in different sizes, but more frequently the size and shape of pumpkins.

No. 2 slope is under and but a few feet to one side of No. 1 slope, so that the loads from it land on the trestle by the side of No. 1 track and connect with it, near the tippie. The loaded cars pass over the trestle in the middle on either side of these tracks, and but a little lower is a track for the empty cars for either slope. As the empty car passes over the tippie it runs up the pitch in a straight track, which has spring latches, and as the car returns it passes into whichever side these latches are open, and passes along the side by force of gravitation, the track on one side being for No. 1 and the other for No. 2. Headblocks keep these empties from running down the slope. When sufficient empties have accumulated on either side they are coupled together, the rope is fastened on, the headblock is lowered, and the trip is rung away for the inside; the slope being of sufficient pitch to carry the empties back into the mine.

The engine house is situated directly under the trestle, a little forward of the knuckle, and consists of two drums, run by a 65-horsepower Jackson engine, which power is to be doubled this summer we understand. A 96-horsepower Norwalk air compressor is also in use.

The steam plant consists of six single boilers with both suction and force draft, the former has a chimney some 65 feet high, the latter a 6-foot steel fan of 250 revolutions. The trestle-work is some 300 feet long, 36 feet high, and about 30 feet wide.

The electric plant is the finest in these parts, and consists of two General Electric generators of 112 horsepower each, run by compound condensing engines, direct connected, of 150 horsepower each. All the mine machinery, such as pumps, mining machines, etc., are connected with the electric plants by an underground No. 0000 B. & S. gauge copper wire, the line being about 2,600 feet in length.

This mine is supplied with a powerful pumping plant and although the flow of water is only about 400 gallons per minute, keeping only one pump in active operation at the present time, yet it can be said that the mine is supplied for all emergencies. The pumps are three in number (located near the bottom of No. 1 slope), i. e., a Dean pump of 1,400 gallons per minute capacity, run by a 150-horsepower electric motor; one Dean pump of a capacity of 600 gallons per minute, run by an electric motor of 110-horsepower, and one Snow pump of 600 gallons capacity, run by compressed air, fed by a 6-inch air line. This Snow pump is held as a reserve in case of accident to the electric plant.

Pictou has been invaded during the past two years by mining machines, the Jeffrey electric chain coal-cutting machines being the ones now most in use. One of these machines will mine from 100 to 200 tons of coal per day. The No. 2 vein seems especially adapted to them, it having a fine sandrock roof allowing the rooms to be driven 100 feet wide or more. The machine work is all contract work, the machine man getting so much per ton and hiring his help.

All machinery in and around the works, excepting the hoisting plant is run by electricity, and the buildings, trestleworks etc., are lighted by it during the night.

Pictou coal is worked by the room-and-pillar system, rooms being driven 7 yards and entries 3 yards wide. Back entries to facilitate the ventilation of the mine are driven parallel to each entry. The main slopes, i. e., Nos. 1 and 2, are driven 7 by 10 in the clear, No. 1 being about 2,400 feet long. It follows down the dip of the coal, and is well timbered for a short distance with sawed timbers, set with about a 6-inch batter, but after the formation is well caught very little timbering is required, except in places. No. 2 slope pitches sharply through the rock formation

at first, until the coal is reached, after which it follows the coal down the dip as in No. 1 for about 200 feet, when it dips down through the rock formation into No. 3.

Both No. 2 and No. 3 veins are worked from each slope, the slopes having been sunk into the No. 3 vein only during the past two years. Most of the coal, since the opening of the mine, has been taken from the No. 1 vein, so that No. 2 and No. 3 are practically untouched. Within the past year the No. 2 slope has been driven on the No. 3 vein, connecting No. 2 slope with No. 1 slope in the bottom, so that now, as will be seen from Fig. 1, the company has a very large field of coal blocked out. The tracks of the mine are laid on pifton ties with a 3-foot gauge. Thirty-pound rails are used in the slopes, while the ordinary rails of the mines are 16 pounds.

Nos. 1 and 2 veins are timbered mostly with pifton props, the pifton is a species of pine that thrives only on the dry rocky knolls of the prairie and along the foot of the mountains, yet it produces a nut, which, with the children of this clime, takes the place that beechnuts do in the East; it looks somewhat like a stunted pine, it does very well for props, however, and as stated, Nos. 1 and 2 veins are mostly timbered with it. No. 3 has a poorer top, being composed of soapstone, and the timbers used in it are chiefly mountain spruce. The entries are all cross-barred, and the rooms are cross-barred over the roadway, the bar being notched into the rib and the other end resting on a leg, two rows of props on the gob side generally completing the timbering of a room. Each 400 feet along the slopes, entries are driven on both sides on a water level, rooms being turned off the entries "up the hill." Sometimes, however, cross-entries are driven up the pitch instead, and rooms turned off at right angles on either side. In such rooms the loaded cars are pushed out of the rooms and spragged down the hill on to the main entry. In the rooms that turn off the main entries the cars are also spragged down to the entry, in either case the driver hauls the car into the face of the room with his mule, and on the entry when he has enough loaded cars for a trip he couples them together and hauls them out to the main slope, here the rope runner attaches them to the cable and takes them outside.

The coal, except where mining machines are used, is mined by shooting off the solid, a 6-foot hole and 30 inches of powder answering the purpose in most cases. For drilling holes for shooting, the post machine is most extensively used.

Drivers, timber men, and all inside company men receive \$2.60 per day, the digger calculates to make more.

The ventilation of the mine is produced by a 25-horsepower "Guibal" suction fan, 20 feet in diameter, placed over a shaft some 60 feet deep, the shaft penetrating through all three veins. Air enters the slope mouths, passes around, and returns to the air shaft at its intersection with each vein, that is, the return air is passed into the air shaft in each vein separately; no air after traveling around one vein of coal being carried into another. As usual in such mines, the air is forced around where it is needed by doors, curtains, crosscuts, etc., and crosses the slopes by overhead bridges. The fan is now run by electricity; its speed being regulated by a rheostat. The steam plant that formerly operated it is also retained so that the fan is now equipped with both steam and electricity.

All underground work is carried on by naked lights, there never having been any difficulty experienced in keeping the workings clear of what little gas is given off by the coal; however the fireboss makes his round every day before the men go in and leaves his chalk mark on the different places.

Before the opening of the coal mines here at Pictou the place was known as Sulphur Springs, the name being derived from a group of sulphur springs that issued from a small rocky hill just below the coal crop. The water was soft, but too warm to be agreeable for drinking, unless allowed to stand over night, when, the gases having escaped, and it having cooled, it was not bad stuff to drink. It was hauled to Walsenberg and sold for drinking purposes, for years, at 40 cents per barrel, and ever since the opening of the mines the "water wagon" has been one of the crying necessities, as nearly all the drinking and cooking water comes from these springs, and costs, delivered around the camp, 15 cents per barrel. Many wells were sunk, but only a few obtained water. The mine has always had enough water to necessitate a fairly strong pumping plant, but this never seemed to affect the flow of the springs.

A little over a year since, after sinking the slope from No. 1 into No. 3, in driving an entry in No. 3, the floor for several feet square hove up and a powerful head of water rushed in, flooding this part of the mine before many of the miners could get their tools out. Through the untiring energy of the superintendent then in charge, the water was kept back from flooding the rest of the mine, while a large electric pump could be ordered, shipped, and placed in working order; then for months the water went down gradually until at last the water was all out, now these

great pumps make holiday sport of this water. But when this water broke into the mine the bottom fell out of all the wells in camp, and these springs that from remote ages had furnished man and beast with a substitute for good water, ceased to exist. In two days' time there was no water in either. Since then the water for the camp has been pumped from the mine; it seems to be the same as that that formerly came from the springs, i. e., a soft water, strongly impregnated with sulphur.

Pictou coal fields lie in the upper Cretaceous formation, i. e., the Laramie. In the "bone" that is often attached to the coal, however, leaves like the beech leaf, and small bivalve shells occur in a fossiliferous state. Above the coal is a thick bed of sandrock that is more or less fossiliferous; some of it has been metamorphosed (apparently by heat) into quartzite, some very fair specimens of reeds of the Laramie coal period occur in this sandrock as also mollusks, shells, and a few ammonites.

A short distance below the coals is the outcrop of a stratum of limerock that contains large quantities of *Baculite* fossils.

encountered, and in driving through it the No. 2 coal is encountered showing an up-throw of over 30 feet. These changes in the coal show conclusively that the dikes are a late acquisition to this country, geologically speaking. These dikes stand up over the country, in some cases, over 100 feet.

Water-Tube Boilers and Forced Draft.

We do not hear so much nowadays about boilers being damaged and trial trips lost on account of the use of forced draft, but about 10 years ago this was a complaint not at all uncommon. A part of the reason for the change is, as will be seen later, the increased use of water-tube boilers; but, nevertheless, the known fact that forced draft can be used within limits on any boiler with decided advantage suggests an examination to determine, if possible, what those limits are.

As was already remarked, the advent of water-tube boilers has removed this question of damage done to the tube ends by high rates of combustion from the region of practical considera-

FIG. 2. VIEWS IN PICTOU

Some of these are very beautiful as they glisten in the sunlight with their coatings of mother-of-pearl and their joints as perfect as the day when first they ceased to live. Below this again lies a thick bed of shale several hundred feet thick. A few miles to the east of Pictou, in lime ledges, occur splendid specimens of ammonites, as also many other Cretaceous fossils. All rocks coming from the mines are strongly impregnated with magnesia.

The nearest mountain, called Silver Mountain, lies about 13 miles to the west; it is a laccolitic mountain, and porphyritic dikes, generally only a few feet wide, extend from it through the foothills and through the coal, cutting it from the east to the west. These dikes, or "hogbacks," as they are called, run parallel to each other, and vary from half a mile to a mile or more apart. These dikes have coked the coal from 15 to 20 feet on either side, and, in some cases, have shifted the formation; as for instance in the "South Side" in Pictou mine, about half a mile from the slope; in an entry in No. 1 vein a dike is

tion, owing to the fact that in well designed boilers of this type, where there is any adequate provision for expansion, there has been no case of damaged tubes, however rapid the combustion. At a recent engineering congress, Mr. C. D. Mosher gave a report of a test of one of his boilers, where the air pressure was 12 inches of water, giving an evaporation of 18.2 pounds of water per square foot of heating surface. In the trial of the Ward boiler, prior to its adoption for the U. S. S. Monterey, the rate of combustion was 55 pounds per square foot of grate for a period of 24 hours, without any damage whatever, and in a short test of the boiler of the U. S. S. Cushing, with an air pressure of 4 inches of water, the rate of combustion was higher than 66 pounds per square foot of grate, without any damage. Indeed, this was one of the reasons which led to the readiness with which the water-tube boiler was accepted, although, of course, the prime reason was the reduction in weight.—Walter M. McFarland, in *Engineering Magazine*.

GREAT SALT LAKE

And Its Waters—A History of the Early Exploration That Led to Its Discovery.

Facts Shown by the Survey Made by the United States Topographical Engineers in 1849-50 and an Account of an Expedition Upon It by the Author in 1891.

Written for MINES AND MINERALS, by Don Maguire.

In taking an inventory of Utah's mineral wealth, it would not be correct to place her great inland salt sea as amongst the small items of her resources. In length this wonderful body of water is at present from northwest to southeast 76 miles, and from east to west, at its greatest width of water surface, a little over 36 miles. The surface area of the waters of this lake is about 2,100 square miles. It is one of the greatest bodies of inland salt water on the earth, and presents one of the most interesting examples of its kind in the world.

The first knowledge of this wonderful body of salt water came to the people of the United States from trappers who were in the service of the Hudson Bay Co., or in the employ of the American Fur Co., or members of what was then known as the Association of Free Trappers, and who, wandering into this then distant drear and unknown region, brought back wonderful tales to the American settlements along the Mississippi relative to an inland salt sea that lay far to the westward, surrounded by steep mountains and barren deserts, the few inhabitants of which were the most barbarous and loathsome of humanity. Even earlier than the 18th century vague statements were made by many of the early French explorers regarding this lake. In the year 1689, Baron Lahontan, the then Lord Lieutenant of the French province of Placentia, in New Foundland, made a voyage of conquest and discovery into the regions of the great west. No doubt the Baron Lahontan visited most of the country along the great lakes, also the Wisconsin River, and still farther west and northwest along the Mississippi and Missouri Rivers, but beyond that he seems to have incorporated into his own personal observations much of the reports and statements made to him by the various Indian travelers and hunters whom he met in his wanderings. The North American Indian was never a good geographer, and as a consequence the map furnished to the world by the Baron Lahontan, for the existence of much of which he depended upon Indian descriptions, is, to say the least, very faulty and vague, and its errors are very many, but not greater than those made by the map makers who for 3,000 years furnished to inquisitive mankind what purported to be maps of central Africa and the sources of the River Nile.

For more than 300 years the region in which Great Salt Lake lies was a part of the immense possessions of the kingdom of Spain, but we are not aware of any report being now in existence made by any Spanish explorer relative to this lake or its surroundings. The expeditions of Coronado and Cabeza de Vaca do not seem to have sent any of their forces as far north as Northern Utah, in which this lake lies, but as these expeditions from

Mexico established settlements in New Mexico and Arizona there is little doubt but that exploration was carried as far north as Great Salt Lake, and even beyond to the South Fork of the Columbia River, or what is now known as Snake River. It is quite likely that members of the Franciscan orders of monks, or the Jesuits from old Spain, in the 16th, 17th, and 18th centuries visited the region in quest of converts to Christianity; but if so we have no record yet preserved to our own times of the fact, and the Indian traditions do not tell of any farther north than the Virgin River in Southern Utah, where Padre Escalante carried on missionary work amongst the wild tribes of that region.

Although the country was a possession of Spain until the time of Mexican independence, it remained a comparatively unknown wilderness, and when Mexico became independent its government was too weak to undertake expensive voyages of discovery into its vast northern possessions. In the meantime the restless trappers and traders of Canada and the United States visited the east shores of the lake, and by the year 1805 the fact of its existence became pretty well known to those interested in western exploration.

The work of Lewis and Clarke, as projected by the Government of the United States, did not extend as far south as Utah, the region being then a Spanish possession, and the country

ceded by France during the Consulate of the First Napoleon reached only to within about 70 miles of the then Spanish boundary line north of Great Salt Lake.

An expedition under the auspices of John Jacob Astor was sent across the country overland from St. Louis, Mo., to Astoria, Ore., on the banks of the Columbia River; but none of the members of this expedition visited the Lake, although they passed down the South Fork of the Columbia, about 140 miles to the north of the north end of Great Salt Lake.

In the year 1833, another expedition of discovery, under the leadership of Captain Bonneville, crossed the plains by way of the South Fork of the Columbia or Snake River, and when at Soda Springs, in what is now the State of Idaho, he organized a side expedition to go from Soda Springs by way of Great Salt Lake, and on to Southern California to the Spanish settlements, and there open

trade with the inhabitants, for which purpose he sent with this California contingent a large lot of merchandise to exchange for furs, specie, or such other kind of exchange as would return a high profit on the venture. The leaders of this expedition were instructed by Captain Bonneville to treat kindly and in a diplomatic way all of the native tribes met with on the way to California, so that in future it might pave the way to pleasant intercourse between these native tribes and the American who might visit the country.

These injunctions were not observed, for the members of the California expedition were no sooner in sight of the Great Salt Lake than they got into trouble with a band of Piegan Indians on the banks of Ogden River. The trouble arose about a few traps which the Americans claimed had been stolen from them by the Indians. A fight ensued in which about 20 Indians were killed, and the members of the California expedition were compelled to leave the region as rapidly as possible, and without obtaining any valuable information relative to the Great Lake. They passed on to California, and returning the next year again met their leader, Captain Bonneville, at Soda Springs. Thus again a very important opportunity was lost to learn something of value relative to the wonderful inland sea. In the meantime various trappers

MAP OF SALT LAKE AND REGION ABOUT.

of more than ordinary intelligence visited the Great Salt Lake Valley and told their comrades much of its wonders. Kit Carson, Captain Sublette, Mr. Ashley, Pegleg Smith, Bill Williams, and Peter B. Ogden each visited the country, and the latter, Peter B. Ogden, a trusted agent of the Hudson Bay Co., established a trading and fur post in Great Salt Lake Valley, on the river that now bears his name, at a point half way between the base of the Wasatch Mountains and the eastern shores of the lake. This post was occupied for many years, and the knowledge of the country thus obtained by its occupants was of much benefit to American officials who visited the country in later years.

In the year 1843, Captain John C. Fremont, on his famous overland voyage of exploration from St. Louis, Mo., to the Pacific Ocean, visited Great Salt Lake, and to him we must give the glory of being the first white man of whom we know who ever navigated the waters of Great Salt Lake.

This took place on the ninth day of September in the year 1843. His companions on this occasion were the famous Kit Carson and two Frenchmen, one named Bernier and the other Basil Lajuenesse.

Their camp was in a bend of the Weber River, where they had prepared a small fort to protect themselves and horses and mules from the Indians. At the fort, Captain Fremont left three persons, Badeau, Deroseur, and a negro named Jacob. The boat used by Captain Fremont, on this occasion, was of rubber and in a poor state for the work to be done.

There was much doubt as to the wisdom of the undertaking, as the early trappers and Indians entertained the most superstitious ideas regarding the lake, even the intrepid Carson did not like the undertaking, but the party pushed forward, and on the ninth day of September, 1843, the first white man who ever put foot on an island of the great lake was John C. Fremont. They landed on what they called Desolation Island, but which is now known as Fremont Island. This island lies about three miles from the east shore of the lake, and about 18 miles west of the present city of Ogden.

They found the island uninhabited and covered over with fairly good grass, also artemisia or sage brush, and what is known in Utah now as greasewood. There were no animals and only one spring, the waters of which were somewhat brackish. The formation of the island they found to be a decomposed micaceous slate, interspersed with bands of quartz in which there existed more or less cubic pyrite.

Remaining over night on this island, Captain Fremont returned to the main land and continued his overland journey to Oregon.

His description of the lake and the island is beautiful, only that he described it as wild and weird. The screaming and clatter and chatter of the countless water fowls, such as pelicans, bitterns, wild duck, and geese, that lined the shores of the lake and floated on its waters, made the air alive with their cries, and the mournful dashing of the surf against the rocky shores was not soon to be forgotten.

But an event was soon to occur that was to change the political condition of this then little known and weird country. War broke out between Mexico and the United States, which ended in California, Utah, Nevada, and New Mexico being ceded to the United States, and thus Great Salt Lake became a Yankee possession. This took place in the year 1847, and in this same year the Mormons, under their leader, Brigham Young, crossed the plains and settled in the valley of the Great Salt Lake, on its east shores, where the waters from the high Wasatch range of mountains afforded them opportunity for irrigating the rich black soil of the valley.

About this time there was an immense immigration to Oregon, and the next year the gold excitement to California, all of which events brought Great Salt Lake into much prominence as an important wayside feature.

It was now, in the year 1849, that the United States Government, during the administration of President Fillmore, ordered an official exploration and survey of the Great Salt Lake to be made. This important work was intrusted to Captain Howard Stansbury, of the United States Topographical Engineers, and on the thirty-first day of May, 1849, Captain Stansbury, having in his party 18 men with five wagons and 46 horses and mules, began his expedition to Utah for the famous survey. For the entire distance of 1,200 miles, from Fort Leavenworth to Salt Lake, Captain Stansbury carefully took notes by the way, touching the flora and fauna of the country passed over, also of the mineral prospects of the region traveled over. The various tribes of Indians met on the way he found friendly, and placated them in every way possible, that those coming after him might the better find them friends. The survey party arrived in Salt Lake City in October, 1849. He, in company with Lieutenant Gunnison, began the work of survey, and for nine months this party were busily engaged in the work of surveying the great lake, the

results of which are our only points of dependence as to area, etc., to this day.

His work consisted, first, in making a journey around the lake, which was in those times a work of danger and suffering, inasmuch as in penetrating the region west of the lake there was neither water nor any kind of forage; and at one part of this journey he was compelled to go 70 miles without water, losing four head of their mules, that perished from thirst.

He was doubtless the first human being who made the journey around the lake, and the distance so traveled by him on this occasion was 412 miles.

The actual distance around the lake, following the water line, is 307 miles, but Captain Stansbury was compelled to follow a course in many places far from the lake, in order to reach mountain peaks to be used as triangulating stations during the survey; and he was compelled to travel far from the lake at many points, in order to obtain fresh water and grass for his pack and saddle animals. On two occasions the entire party came near to perishing for want of water, and it was with the greatest difficulty that they at length reached the green meadows that existed then near where the town of Grantsville now stands, 40 miles southwest of Salt Lake City. In crossing the 70-mile desert west of the lake, Stansbury came across the wreck of an emigrant train which two years before had attempted a passage of this route on their way to Oregon. The persons composing the party either succeeded in making their escape by abandoning their wagons and animals, or else wandered away into the desert farther west and perished. In the wagons so abandoned in the wilderness Captain Stansbury's party found abundance of merchandise, clothing, guns, scientific instruments, medicines, drugs, women's wearing apparel, and even jewelry. To this day the history of this lost party is unknown. What a beautiful opportunity for the novelist!

Early in the spring of 1850, Stansbury continued his work of survey of the lake. Every island of the entire lake was visited. Of these islands there are eight, viz., Antelope, Stansbury, Carrington, Hat, Fremont, Egg, Gunnison, and Dolphin; the largest being Antelope, which is 16 miles in length and 5.25 miles in width at its widest point. Stansbury Island is next in size, which is 11 miles in length by 4 miles wide. Fremont Island is 5.50 miles in length by 1.5 miles in width. Carrington Island is 2 miles by 2 miles in area. Egg, Hat, and Dolphin islands are small insignificant dots in the lake, without water or soil, and are only the nesting places of various timid aquatic birds.

Antelope Island is an oblong mountain rising out of the lake, its highest point being about 3,000 feet above the lake's surface. On its sides near the summit there is considerable piñon pine, cedar, and juniper, and on its east side a number of fine fresh-water springs, with a considerable area of excellent soil. On Fremont Island there is only one spring of water, and this is quite brackish. On the remaining six islands there is no water. Captain Stansbury's survey of the Great Salt Lake was most exhaustive. He visited every island, went around the promontory that runs 16 miles into the lake from the north, and made 93 soundings at different parts of the lake. Adding together the various depths so obtained, and dividing them by 93, the number of soundings, we find the average depth of the lake at that time to have been 13.25 feet, and the greatest depth found was 36 feet, and a great part of the lake's depth was found to be from 16 to 30 feet. The above survey was completed in the year 1850, and Captain Stansbury and his party returned to Fort Leavenworth in the autumn of the same year. His report was issued by the United States Government in the year 1852, and remains to this day the most exhaustive official report on America's inland sea.

The writer will now turn from the reports of Fremont and Stansbury to his own observations and discoveries upon this interesting body of salt water. He first visited the lake in the year 1871, 22 years after Stansbury had completed his survey. Even in 1871 the shores of the lake were little frequented save by a few cattlemen who pastured their herds on Antelope Island, and also, during the winter months, on Stansbury Island. Returning to Utah, some years after my first visit, I desired seeing the various islands of the lake, also the promontory, and to measure the depth of the lake westward from Ogden to its western shore, as I then believed that a railway could be built across the lake to Lucine on the Southern Pacific Railway line, thus cutting off the great horseshoe formed by running up to Corrine and promontory and thence over sharp inclines and grades to Lucine.

For the purpose of making this voyage, my party used an old staunch sailing boat, built at Farrington, on the east shore of the lake. She had been constructed to carry wood and cattle from Antelope Island to the east shore of the lake. This vessel was about 75 feet long and 16 feet across the beam, very strong, and well suited to resist the terrible squalls that are so common on Great Salt Lake, and named the Argo.

Three persons accompanied the writer, Daniel McEa, a newspaper editor, of Salt Lake City, Matson M. George, and Auth Edwards, of Ogden, Utah. To manage the vessel we had for a captain one George V. Mortin, who in his early years had been a skipper in the Indian ocean, a young English sailor, a Calabrian whose life had been spent around the stormy coast of Eastern Sicily, and two Portuguese sailors. We had on board the vessel water and food supplies for a two weeks' voyage, and feeling ourselves secure for the work in hand, we left Syracuse bathing resort, on the east side of the lake, in the latter days of July, 1891.

With good weather and fair wind I do not think there is a more agreeable body of water upon the earth's surface on which to sail than Salt Lake. Our first evening's sail brought us to a small bay on the southeast coast of Fremont Island. We dropped anchor at 8 o'clock in the evening. The water at this point is as clear as crystal and the depth about 12 feet, with a gravelly bottom on which millions of white quartz pebbles lie scattered. The night on which we anchored here was favored with a full moon, and the sky was perfectly clear, and the low wind created enough ripple to give a pleasant sound as the tiny waves beat against the shores of the island. On the clear air of evening we could distinctly hear the quacking and snapping of the pelicans that have their habitation on Pelican Island, many miles to the westward. There is an indescribable grandeur and majesty in a moonlight scene on this lake. The Wasatch Mountains, to the eastward about 16 miles away, seemed to rise up to double their natural height, and their bold, wild, and ragged outline rose clearly against the sky, and equally so with the ranges south and southwest.

Our supper was eaten on the deck of the Argo, and in the soft moonlight we planned our work and our probable discoveries during the week to come.

Being well acquainted with the explorations of Fremont, Stansbury, and others who had sailed over the waters of this wonderful salt sink, my mind wandered back to the days when those two men, now in their graves, anticipated the strange sights they were to behold in the lake and on its many islands, just as we were about to do. What a strange old history from a geological point of view this lake has known. From the ancient days, when its waters covered well nigh ten times its present area, when it was a broad fresh-water lake, and poured its mighty tributaries into the Pacific Ocean by way of the Portneuf, Snake River, and Columbia. In those old days its waters teemed with abundant fish life. It was well nigh 600 feet in depth, and in winter its surface was covered with thick ice, which, breaking in the spring, was swept by the southwestern winds against the eastern shores, that extended, in those days, far up upon the Wasatch Mountains. On these sections of broken ice that floated from around the islands were carried great quantities of the micaceous slate fragments, that, beaten into a pasty state and mixed with white quartz pebbles, formed, later, a sort of conglomerate, and which now resembles a porphyry as we find it along the base of the Wasatch Mountains.

In those ancient times, what is now known as the west range of mountains, or Brigham range, was an island in this fresh-water lake. The tremendous precipitations and extreme humidity nourished a dense growth of timber and vegetation on the surrounding ranges where now there is only sterility. Mountain floods carried down into the lake immense quantities of timber that soon settled water-logged at the bottom of the lake, and which now, hundreds of feet below the present bottom of this lake, are being converted into coal for the men who are to do business in this old world of ours millions of years hence.

How long this state of things continued on Salt Lake we know not. The geologists of our day give the name of Lake Bonneville to this lake, as it then extended along the foot of the west mountains at Black Rock, southwest of Salt Lake City, and near Hot Springs north of Ogden. We can easily count 13 stages at which the ancient lake stood during the various stages of its existence.

What now constitutes the American Desert, west of Salt Lake, also Cache Valley, Ogden Valley, Utah Valley, Cedar Valley, and Shull and Rush Katties were under the same vast fresh-water lake, and fed by rivers, the very outlines of which disappeared thousands of years ago. We do not know the cause of this rise in the waters of the ancient lake, nor how long they thus stood, nor the cause of their decline, until falling within the present basin line they grew salt as they are today. It is quite certain that at one time the lake was much lower than at present, as we find terraces below the present water surface around the islands and also along the promontory that extends into the lake from the north. It is quite likely that the period which saw the flooding of Great Snake River Valley, with its present fields of lava, saw equally great changes in the Salt, or Bonneville, lake basin. Doubtless at that time were born many of our present chains of mountains, and a new Pacific shore line gave a new climate to our present intermountain country of the West.

The morning of our first day on the lake broke clear and

rosy. We ate breakfast, and lowering our lifeboat, we landed on Fremont Island, then occupied by the late Judge Wenner, a native of the State of Michigan. This gentleman, a lawyer by profession, and then acting as probate judge of Davis County, Utah, chose this lonely island as his abode, on account of lung trouble from which he suffered. His wife and three beautiful children here shared his exile. Sharing their exile these good people had on the island about 5,000 sheep, the profits of which returned a fair revenue to the judge. Leaving the home of this isolated household, we began our exploration of Fremont Island. We found it somewhat of the shape of a crescent, the hollow of the crescent being to the west, and the length of the island about five miles, with a width of scarce a fourth of its length. The formation is micaceous slate resting on quartzite, the quartzite being so rifted and altered by heat as to much resemble porphyry. The slate is filled with microlites, is soft but very tough, and if properly mined could produce excellent roofing slate. The only ill feature it possesses is that much of it contains cubic pittings caused by cubic pyrite it once contained, but which, becoming oxidized near the surface, left the cavities that now exist. On the island we found the one spring made note of early in this article, its waters quite brackish but not unpalatable after continued use. The northern part of the island rises 800 feet above the lake, and at this northerly point there rises a high terrace, which, from the mainland, looks much like an old fortress or castle. At the north end of this high elevation exists the only monument or sign left by the early explorers. It is a cross cut into the face of the rock. It is somewhat oblique, about 8 inches in the upright and 5 inches in the cross-arms. Lieutenant Stansbury discovered it and makes mention of it in his report. Col. Fremont does not, for which reason I am inclined to believe that this cross was made by one of the two Frenchmen who accompanied Fremont to the island in 1843. There is no date accompanying it, nor name nor initials. Were it not made by Fremont's men, then it must have been made by some of the earlier and unknown Spanish explorers. We ascended to the summit of the island, and after taking the altitude and gazing out upon the western part of the lake and its queer looking desolate islands, we returned toward the shore, examining minutely the formation. The measures of slate covering the island contain many veins of white quartz, and thousands of crystals of pyrite altered to limonite protrude from the slate surface and along the beach, and one may pick up thousands of limonite iron pebbles and pebbles of white quartz, formed from broken vein matter, out of the slate. The quartz which abounds in most of the State, in the small islands of Great Salt Lake carries no gold nor silver nor other valuable metal. Very small seams of copper ore appear in places, but not of sufficient promise to warrant working for the metal contained. On the east side of the great cliff, and near where there is a small cave, we discovered a small vein in the metamorphic slate that was what may be termed sal ammoniac in a natural state. Doubtless caustic saline solutions had much to do with its formation.

The entire expression of this barren and desolate little island would indicate at one time great volcanic action, as do also all of the small islands of the lakes. There is a sort of magma found on these islands which I have seen nowhere else on earth. It is made up of a matted slated and in this are imbedded irregular and sharp-shouldered masses of quartz and feldspar. There are immense cliffs of it on this and other small islands, and Hat Island is made up of this matter almost entirely.

A few hours' study of Fremont Island forced the conclusion that the promontory, Fremont Island, and also Antelope Island are a continuation through the lake northward of the Oquirrh, or Brigham, range of mountains. The formation of Antelope Island and the mountains of the promontory are similar and one with that of the Oquirrh range.

The promontory which lies immediately north of Fremont Island is 16 miles long and 6 miles at its greatest width. It is a rough mountain range, rising out of the lake and extending northward toward Snake River. The highest point of the promontory is a little over 7,000 feet above the surface of the Gulf of Mexico. On the eastern slope of the promontory there are several thousand acres of good land, and five springs of excellent fresh water. This land and water are owned at present by ranchmen residing on the promontory. In the cañons of this strange mountain chain there is much mountain maple, cedar, juniper, piñon pine, service berry, and dwarf oak, with excellent bunch grass, with also an immense area of the whole surface covered with artemisia or sage brush. The western slope of this promontory is like the western face of all our mountain chains in Western America, quite abrupt, showing the ragged escarpment made at the time of upheaval; and on this western side the strata forming the whole range are very distinct, consisting of Carboniferous limestone, slate, and quartzite, with an occasional outcrop of syenite at the base. I was most favorably impressed with the mineral indications existing on the promontory range;

silver-lead ores, and copper should exist there in abundance. The copper which I found there occurred as float, but would indicate the existence of very strong veins in the older rock, from which it had been carried by the elements.

On Antelope Island the formation is quite similar to that of the promontory, save that there are more extensive veins of iron ore existing in the slate, and accompanying it there are a few good veins of copper associated with gold and silver. On Antelope Island there are large herds of cattle and horses owned by residents of Salt Lake City, and other herds of cattle pasturing there are owned by people living on the island. There are several large springs of sweet water, excellent soil on the east side, and in the mountain parts of the island we found abundance of piñon pine, cedar, and mountain maple.

On Carrington Island and Stansbury Island there is good grass but no water; as a consequence they are seldom frequented. The smaller islands are utterly barren.

We visited every island of the lake, crossed the promontory, and made measurements of the water depth at different points. The greatest depth found was at a point about 5 miles southwest of Fremont Island, where the water measured just 70 feet, showing that there is at that spot a greater depression than elsewhere in the lake so far as known. Far out from shore the waters of the lake are very clear. At the point where the depth registered 70 feet, we could distinctly see the white bottom, over much of which a spreading marine plant grows in quiet luxury.

The waters of this lake carry in solution from 17 to 21 per cent. salt. It is so much more saturated with salt than the brine of the ocean, that hardly any life exists in its waters, the only exception being a small, semitransparent monster about half an inch long and one-eighth of an inch wide, possessed of most conspicuous and protruding eyes and antennae or forearms that are actively employed in swimming. This little creature is not unlike a crab in appearance, and is the only inhabitant of the briny waters of this lake. It is found swimming in shoals or schools, and it is not present at the same time in all parts of the lake. Neither Fremont nor Stansbury makes mention of these fellows. They are almost transparent and exist in immense numbers. They abound in Great Salt Lake, also in Mono and Owens lakes, in eastern California. Their eyes are conspicuous and the body a jelly-like substance. They are known to science under the name *artemia fertilis*.

The waters feeding Great Salt Lake flow out of Bear River, its largest tributary, also from Box Elder Creek, Willard Creek, Utah Hot Springs, Ogden River, Weber River, several mountain streams that flow from the Wasatch Mountain, in Davis County, the Hot Springs north of Salt Lake City, and also from the waters of Jordan River, which in turn forms a connecting link between Great Salt Lake and Utah Lake, a fresh-water body that lies 40 miles to the southward, in Utah Valley; and the streams feeding Utah Lake are Provo River, Spring Creek, Pond Creek, Santa Quin Creek, Salt Creek, Spanish Fork, and American Fork Rivers. All the above streams flow down from the great Wasatch range of mountains save Bear River, which drains a country farther east.

During recent years the volume of water flowing directly into Salt Lake from the above streams has materially lessened on account of the vast volume of water used from these streams for irrigation of lands of Utah and Salt Lake Valleys. Many argue that the waters of the lake for the above cause have receded from the shore lines of early settlement times. This, however, is a mistaken belief. The area now covered by the waters of the lake differs very little from the area which they covered in 1849, when Lieutenant Stansbury made his survey. It is quite true that there seems to be periods of increase and decrease of the lake's volume, the true causes of which we do not yet understand; but there is comparatively no change in the average year's volume of water present.

It has been said, by many, that there is a subterranean discharge from the lake. This is also an error. Evaporation, which is great in the arid region of Utah, accounts for all of the water that disappears from this great lake.

In our own times this lake is yearly receiving new volumes of salt from many springs that flow into it, some of which are situated as far south as Salt Creek Cañon, in Juab County, almost 100 miles away. The waters of these distant springs flow first into Utah Lake, and although the volume of salt is not sufficiently great to be easily perceived by drinking the water of Utah Lake, yet it is there in solution, and with the discharge of Utah Lake into Salt Lake this salt ultimately finds its way into the latter great salt-sea reservoir.

As to the cubic measurement of salt contained in the lake at present, allowing it to be 20 per cent., the volume of water and the average depth of the lake to be 13.75 feet, and the area of the water surface to be 2,100 square miles, were the waters of the lake to be evaporated there would remain about 2½ feet of good pure white salt over this vast area of 2,100 square miles.

Allowing 332 pounds for each square foot of the vast area of 2,100 square miles, gives us an idea of the vast volume of salt existing in this lake.

For 30 years large quantities of aerated, or air-dried, salt have been gathered along the east, south, and southwest shores. Hundreds of thousands of tons of this salt have been shipped into Nevada, Montana, Idaho, and various parts of Utah, for use in the treatment of silver ores. Immense quantities are used for household use in the Western States and Territories, and also as stock salt. Analysis of the waters of Salt Lake, made by Captain Fremont in the year 1843, gave 14 pints of fine salt from 5 gallons of the salt brine, and the analysis of the salt so obtained gave as follows:

	Per Cent.
Sodium chloride, or common salt	97.80
Calcium chloride	0.61
Magnesium chloride	0.24
Soda sulphate	0.23
Lime sulphate	1.12
	100.00

The analysis of today differs very little from that made by Captain Fremont over 50 years ago.

I have diverted the attention of the reader from the events and cause of our voyage of discovery on Salt Lake, in the year 1891, in order to depict the main and most interesting features of the most interesting body of water. To resume the records of that voyage, I will state that we were engaged for nine days making the voyage around the lake, during which time we encountered most terrific squalls and protracted wind storms, proving that even in summer Salt Lake is subjected to wild and dangerous storms, thus necessitating the use of strong and good sailing vessels by those who desire making the voyage. The student is well repaid for the toil incurred in that achievement. Strange to relate, although our vessel, the *Argo*, often stood on her beam ends during the storms we encountered, and we rocked for hours, yet even those who had never been a day at sea did not experience seasickness during the voyage.

The results of our voyage were some hundreds of plants, some scores of beetles, butterflies, lizards, horned toads, and about a ton of the various rock formations of the different islands and the northern promontory. In looking back to the events of that voyage, it remains a milestone in my life and an event not to be soon forgotten.

During the past 10 years several noted bathing resorts have been established on the shores of the lake, the chief of which are Garfield Beach and Salt Air. Neither money nor pains have been spared to render these places attractive, and a very large patronage is given them during the summer months, being reached by railway lines and within a few minutes' ride of Salt Lake and Ogden cities. They who come to Utah during the bathing season usually visit them. Bathing in this water is most extremely invigorating. There is a buoyancy about the water that sustains the body without effort, and those who once use its waters never fail to visit them again. These waters are said to be excellent for somnambulism and a cure for many nervous disorders. There is one feature highly necessary in bathing in this lake. Woe be unto her or him, while bathing in these waters, who should be far from the shore or vessel when overtaken by a squall. The caustic nature of the brine is such as to blind, temporarily, the eyes, and if the water reaches the throat and nostrils, strangulation is almost certain to be the result. Few deaths, however, have been recorded in this way, as caution is usually observed. Where persons are thus drowned, and the bodies are washed out into the lake, they are carried into deep water, and, reaching the shore of some of the desolate islands, usually mummify in a few months, if not found soon after death.

The time is not far distant when Great Salt Lake will be made the scene of extensive manufacturing works. At either Salt Lake or Ogden the manufacture of caustic soda, chlorine gas, and the various alkalies that are entering so largely into our industrial requirements every year, and every year increasing, may be prepared in immense quantities from this salt brine. The volume of salt present in the lake is practically inexhaustible. Ten thousand years will not exhaust the quantity available, and the ease with which it may be obtained places the cost of salt production at less than \$1 per ton, when gathered into piles along the lake shore. Of late years the Inland Salt Co. has handled most of the salt taken from the lake, and the dairy and domestic salt so prepared is unsurpassed by any salt produced elsewhere in America. During the summer of 1899 there was a salt palace exposition held in Salt Lake City. The palace or building constructed for this purpose was very beautifully prepared. In keeping with its mission, crystallized salt largely entered into its decorations, and in this structure the genesis of Great Salt Lake and its possibilities were pretty well represented.

The climatic influences of the extensive salt-water surface of this lake are such as to render the region of Central Utah one

blessed with a delightful climate. In summer it moderates the heat and in winter softens the wild winds that blow across it. No ice forms on the lake in winter, and in summer its waters are sufficiently cool to temper the winds that flow across them from the hot deserts to the west and southwest of the lake. There are no groves of timber at any point along the lake shore, but on the eastern sides of its desolate islands enough driftwood may be found for fuel to meet the demand of the occasional visitor who seeks these shores. Such driftwood is washed down the waters of Weber, Bear, and Jordan rivers during seasons of freshets, in the months of May, June, and July.

THE PREVENTION OF LEAKS

At Mines—The Importance of System and Attention to the Little Things.

Written for MINES AND MINERALS, by L. C. Morganroth.

One of the greatest assistants to a foreman in combating leaks at his plant is through a properly prepared cost sheet. When he can see, through a clear and concise statement, where his various supplies are going and what they cost; what each department of the plant has cost to operate for the month, with a chance to compare it with previous months, he is 50 per cent. better prepared to combat the little extravagances. The pride in keeping down his expenditures develops those qualities which have rendered the men in charge of the various plants so resourceful and intelligent.

A man employed in cleaning the safety lamps in use at a very gassy mine had a neat little device to assist him in his work. His office was heated with steam from the boiler plant, and a small piece of pipe had been connected to one of the coils and led to a window, extending a few inches outside. The end of the pipe was provided with a nozzle giving him a steam blast to clean gauzes. By means of a lever he could shift a small wheel in front of the blast, which, revolving, caused his brushes used in putting the finishing touches to the cleaning to rotate. These little devices enabled him to do one-half again as much work as if performed entirely by hand. At the same colliery, the cars were delivered to the breaker by means of a tail-rope system. The rope attached to the front end of the trip was connected by a simple, ingenious device which automatically released the rope when the trip reached a certain point. By means of this the services of one man were dispensed with. The mine cars in use were slightly modified, only slight changes, yet lengthening the life of the car considerably. A neat little device was in use by which the hoisting ropes could be tarred while running. The foreman in charge had evidently had some experience with breaker fires, judging by the means he had adopted to combat it at this plant. Fire plugs were scattered at convenient points around the entire plant, with coils of hose conveniently arranged to be attached in the shortest possible time. Inside the breaker, short pieces of hose were directly connected to the pipe line, through which the breaker pump forced the water used in washing the coal. Every point of the breaker was commanded by at least one of these hose. It required but the turning of a single valve to have a stream of water on. At numerous convenient points, barrels painted a conspicuous white were scattered and kept constantly full of water. Immediately above each barrel hung two fire buckets, while in a rack were three or four hand grenades. A regular fire drill was indulged in at least once a month, and a regular inspection of all the apparatus was made once a week, a report being made and filed of the same.

A busy mechanic in a mine, among whose manifold duties was included the running of a small pump, fixes up an alarm to notify him, when away from the pump house, when the sump is full or empty. It is only a discarded engine whistle, with a few crude repairs, connected by means of a small pipe to the main steam line. The whistle lever, by means of a rope or wire, is connected to a float in the sump. The latter rising and falling with the level of the water, causes the whistle to blow when it is either necessary to start or stop the pump, a few crude levers and pulleys transmitting the movement of the float in the proper direction and with the requisite amount of leverage to blow the whistle. In case the sump becomes empty during his absence, the steam is automatically shut off from the pump. It is not altogether the neatest looking affair, yet efficient and made from what material and with the tools he had at hand.

At a boiler house at this colliery, where mechanical blast had been substituted for the customary steam blower, the increased amount of clinker formed, with the increased difficulty in detaching it from the grate bars (generally the result of the dry air blast), was obviated by admitting a little steam to the fan used in furnishing the blast. A small pipe led from the exhaust of the

engine used in running the fan, to the fan. By means of a valve the requisite amount of steam could be controlled. Thus, all the advantages of the air blast was obtained without the corresponding disadvantage of the increase in the amount of clinker formed. This was a device of the boiler man in charge—a level-headed but illiterate man. He could not read, and consequently saw no technical journals. It was merely the outcome of his own shrewd observations and experiments. It is not presented as the original idea, but it was original with him. He had also constructed a neat little arrangement to automatically admit and shut off cold water to his feedwater heater.

One of the most prolific sources of waste formerly at a colliery, and is often yet, was in the use of oil. The extravagance in this one article was enormous, often 100 per cent. more being wasted than used. Oil, when but a drop or two was needed, got 50 or 100 poured on, the machinery generally being oiled by a boy, with all a boy's irregularity and carelessness in attending the same—now swimming in oil and then absolutely dry. Isolated fans and pump houses had a barrel of oil handed them, and the head was knocked in and the oil thrown at the machinery with a tin cup. Mine cars were considered sufficiently oiled when a well defined line of grease extended from the oiling stand to the tippie or the mines or both ways; while frequently the spokes, axles, and body of the car were well oiled, for various reasons. One-half of the oil wasted was due to the poorly constructed oiling devices used on the wheels, possibly oiled through a hole or two, located at convenient points on the hub, and which are supposed to be kept closed by a cap either closing with a spring or screwing in; all right for a time, until the mine dirt clogs up or cuts the threads, or the springs break or are lost; then the cap refuses to work, is lost or deliberately thrown away. Consequently, on each revolution of the wheel two or three little spurts of oil, depending on the number of these oil holes, lubricate the ties on either side of the rail as long as there is any oil to run out. But lately the writer saw a plant where the cars on leaving the mine ran on a trestle where they were oiled. This trestle was one mass of oil. It must have been positively dangerous to drop a lighted match on it. A mixture of pasty oil and dirt formed a ridge along each rail, as high as the rail itself, and on both sides of it. Underneath the trestle two regular little mounds extended the entire length of the trestle. Barrels of oil must have been wasted here annually. Of late, car wheels are being improved by which this source of waste is reduced, several good ones being on the market at present. But the general waste of oil can only be obviated by getting its distribution down to a system. Such is now becoming the general practice. No more scattering oil around in barrels, at convenient points, where it can be gotten at by anybody, at any time. Now all oil is given out at a central station. It has been determined exactly how much oil is required for each and every piece of machinery about the plant, and the man in charge of each machine is furnished with an exact amount, which must last him a stated time. It is ample enough to oil all the bearings, but absolutely none is allowed for waste. The same in oiling the mine cars. The oiler has sufficient to oil his cars, but no extra amount to decorate the sides of the cars with frescoes. The runner of the mine locomotive cannot leave his engine standing idle for an hour or two and his cylinder lubricators open to feed oil in cylinders that are not working. It is surprising how much a man can save when he has to. There is no skimping in the supply, but there is absolutely no allowance for waste, and consequently there is no waste, every one being held responsible for his own machinery. With the amount of oil for the same having been determined by careful and conscientious tests, by an expert, he has no excuse to offer if his supply of oil does not last him the allotted time.

The improvement in all machinery used about the collieries is noticeable. The boiler plants are most modern. Automatic stokers, improved grates, diffused air blasts, ash and coal conveyors, cause the boiler plant to be run as economically as if situated a thousand miles away from the nearest mines. While every improvement in machinery in a general way is toward cutting down the expense and waste incidental to its use, there are still numerous ways by which the leaks can still continue, and are only to be reached and remedied by the man in direct charge—the man with the eye to see and the ingenuity to remedy.

At the last meeting of the American Society of Mechanical Engineers, the veteran engine builder, Mr. Charles T. Porter, in his discussion of Dr. Thurston's paper on "The Steam Engine in the Close of the Nineteenth Century," stated that it is a principle of the New Engineering that "the boiler furnace shall be independent of natural draft, effectually consuming its smoke, and burning two or more times as much coal per square foot of grate as it could do under natural draft alone, and yet sending off the gases at a low temperature; the boiler being a steam generator, a superheater, and a fuel economizer combined."

GOLD DREDGING

In British Columbia—A Description of the Dredging Plants and Methods of Operation Used on the Fraser River.

Written for MINES AND MINERALS, by R. Luid Watson.

Gold dredging was inaugurated in New Zealand in 1868. The first dredge, though crude, served its purpose, for from it has been evolved the modern dredge with all its latest improvements.

In British Columbia, within the last 12 or 15 years, several attempts have been made at dredging in the Fraser River. All were failures, with the exception of one at Boston Bar, three miles below North Bend, built in the fall of 1897.

The earlier dredges were designed to work either by "suction" or "endless chain with buckets." Both types were unsuccessful, because of the nature of the bed of the Fraser, composed as it is of large boulders and cement.

The suction dredge, worked by means of a centrifugal pump, was expected to draw or suck up material from the bed of the river and deposit it in sluice boxes, where it could be washed and the gold separated from the gravel. But trial proved that suction could make no impression on the cement. The attempt to have a diver go down to loosen the cement also ended in failure.

The "endless chain with buckets" type was unsuccessful, because the machinery was too light, and the buckets were not of such a shape as could cut into the cement.

The '97 dredge, built by Beatty & Co., of Welland, Ont., is of the "dipper" type.

The plant rests on two scows, each of which draws about 2½ feet of water. On one is erected the machinery, consisting of a 75-horsepower engine, boiler, pump with a discharge of 500 gallons per minute, the arm that works the dipper and the dipper itself; on the other scow, anchored alongside of the first, is constructed the grizzly, across which extends a water pipe connecting with the pump before mentioned; below the grizzly are the sluice boxes.

The grizzly is composed of iron bars laid about 1 inch apart. Into it the dipper discharges its load. The finer material at once passes through the grizzly into the sluice boxes, washed down by the water coming through the holes of the perforated water pipe. Large boulders and the heavier gravel are carefully washed by a man stationed at the grizzly, who throws the worthless material into the river.

The entire string of sluice boxes is 120 feet long, the first 30 or 40 feet being 3 feet wide, the balance 6 feet wide—in the latter part mercury is used.

The dipper is constructed of cast iron with a steel lip protected by steel prongs necessary to penetrate the cement. It has a capacity for raising 1 cubic yard of gravel each trip, and can make two trips in three minutes. The dredge works to a depth of 25 feet. Most of the gold is found in the cement adhering to large boulders. The scow on which the machinery is built, has house room for the crew during the season. The length of season depends upon the state of the water and the winter. Very high water or the running of ice prevents working. In case of ice, a hole is made in the bank and into it the scows are run.

This dredge has been successful; but it has been working the greater part of the time on Boston Bar—composed to a large extent of loose sand and gravel—only a comparatively small proportion of the time has it operated on the cement.

The latest dredge constructed on the Fraser River is near Lytton. Its machinery is designed after the most modern of New Zealand dredges, and was manufactured by Robey & Son, of Lincoln England.

Some idea of the massiveness of the plant may be gathered

from the illustration, and by considering the fact that the total weight of the dredge housed in—excluding the weight of the tailings elevator, but including all gold-saving devices—exceeds 400 tons.

The boilers have a capacity to generate steam of 250 horsepower. 125 horsepower is required to revolve the buckets which scrape the bottom of the river and bring up the material from which the gold is to be saved; the balance of the power is required to run electric motors connected with the pump and the revolving screen, and will furnish power to run the tailings elevator.

The winches shown on the right-hand side of the illustration are four in number, and controlled by levers so arranged that one man can handle the entire machinery on the starboard side of the dredge boat; another man is required on the port side to attend to the boilers and engines.

The principle upon which this dredge is designed is similar to the endless chain with buckets. Two of the buckets with the two links connecting them weigh 2,100 pounds, empty, and have a capacity of raising 5 cubic feet of material in each bucket. There are 36 of these buckets connected by heavy links, the whole revolving at whatever rate of speed is deemed advisable when the material the dredge is working in is taken into consideration. A study of the illustration showing the machinery in place reveals the string of buckets as they are traveling along the ladder towards the large cog wheel, at which point each bucket is automatically dumped. After discharging its load the bucket passes down into the river and resumes its scooping operations.

So minutely is all the machinery adjusted that whenever a

bucket in running along the bed comes in contact with any specially large boulder or material which offers resistance, the man attending to the winches can tell in an instant that something is wrong, and by a movement can stop the machinery, and by another movement can swing the line of buckets to right or left of the point of resistance, by which means—in case of resistance being offered by a large boulder—an extra deep hole is cut out and the boulder allowed to topple over into the excavation; or, if this cannot be accomplished, by reason of the boulders being too firmly embedded or too large, another movement of the lever would lift the string

DREDGE OPERATING NEAR LYTTON, B. C.

of buckets passing along the bed entirely over the obstacle, and at the same time another lever could be used which would tighten the head lines by which the dredge is secured to the banks of the river, thus working the dredge forward so that with another revolution the line of buckets would be clear of the obstacle.

A bucket is manufactured in three pieces: the bottom, or base, is of cast iron of the toughest description, charcoal Swedish or Scotch pig iron would probably be best adapted for the purpose; attached to the base is a steel side; to the side is attached a lip of hardest steel manufactured, which, it is estimated, will be sufficiently hard to cut into any description of cement found composing the bed rock of the channel.

The depth to which dredging operations can be carried on is regulated by the addition or subtraction of one or more buckets from the chain. It is estimated that the greatest depth to which it can work satisfactorily is 40 feet.

Material hoisted in the buckets is dumped into a revolving screen made of boiler iron punched with holes ¼ inch in diameter. The screen is 20 feet long; through its entire length extends a water pipe connected with the pump, which has a capacity of raising and discharging 2,400 gallons of water per minute. Of course the water pipe is stationary. As the screen revolves around it, water is discharged from numerous holes, not only thoroughly washing the material dumped from the buckets but, by the pressure exerted, tearing the cement to pieces, and thus aiding the revolving screen. Since all material which enters at one end of

the screen has to travel about 150 feet before reaching the discharge end, it can readily be understood that the working of the screen added to the pressure of the water will have a crushing capacity sufficient to grind the gravel to such a degree of fineness as to release all the free gold from the quartz matrix and permit it to pass through holes in the screen onto tables. The tables are arranged under the screen with a slight inclination; on them the heavier particles of gold are saved, while the lighter particles and waste or sand pass over the tables into the sluice, which is at right angles to the tables and extends beyond the end of the dredge a sufficient distance to save all the gold. The method of catching the gold on the tables is gravity—the tables are covered by wire netting to act as riffles. Mercury is used in the sluice box to save the finer gold.

The tailings consisting of gravel and sand too large to pass through the perforations in the screen, proceed to the elevator. This tailings elevator is not shown in the figure because it had not been installed at the time the picture was taken, but the framework for it is shown above the screen. The elevator is so arranged that the tailings are dumped at some distance from the side of the dredge instead of immediately in the rear. Such a method of dumping permits of the dredge being backed from the location of its working, which could not be done if the dumping were immediately astern of the plant.

By the discharge of so much material and water from the screen it would at first sight appear impossible for any substance, however high its specific gravity, to remain on the tables under the screen. It must be remembered though, that the screen is about 4 feet in diameter, and that although an immense amount of material and water is discharged into it during 24 hours, yet the holes, being only $\frac{1}{4}$ inch in diameter, permit but a small proportion of either water or material to pass onto the tables. It is estimated that little outside of gold and black sand, with their proportion of water, will find its way through the holes to be received by the tables. The balance of the material and water is discharged into the tailings elevator. The area of the series of tables is 20 ft. $\times$ 22 ft.

Only one feature of this dredge calls for adverse criticism, viz., the direct dumping of the buckets into the screen. While this course will work satisfactorily in sand or small-sized gravel, when you come to consider the problem of hoisting a large amount of material consisting of boulders weighing from 100 to 500 pounds, it would seem that dumping such material into the screen directly from the buckets would make the wear and tear of the revolving screen so excessive as to seriously interfere with profitable results.

Of course this difficulty might be overcome by stationing a man at the bow to remove any materials from the buckets revolving from the river, which he considered too large or too heavy to be dumped into the screen. The adoption of such a course would tend to depreciate the capacity of the dredge, and, consequently, make operations more expensive and results less satisfactory.

Had a grizzly been constructed to receive the material directly from the buckets and to automatically dump all material too large to pass between the bars of the grizzly into the river, thus allowing only comparatively light material to pass into the screen, then, according to our judgment, this dredge would apparently be as nearly perfect as it is possible to construct such machinery.

The valleys of the Fraser and Thompson rivers were apparently excavated at the close of the Miocene period. During the glacial period that followed, these valleys were filled with boulder clay. In the postglacial and modern periods, when the country stood at its present level relatively to the sea, rivers cut through the drift-filling, and, swerving from side to side, produced a series of terraces or benches. These terraces, thus represent the bed of the river at a former stage in its history.

In '57, '58, and '59, when placer mining in the Fraser and Thompson rivers was at its height, fully \$1,500,000 worth of gold was washed from the beds and benches with the rocker and by sluicing. The pay streak in the benches was found near the surface, the general mass of material composing the terraces was not payable worked by such rough methods. What was not profitable worked by primitive means might easily yield good results to more improved methods. Terrace materials especially in the vicinity of the mouth of a stream flowing from a known auriferous locality would justify test operations. But the present dredging law in British Columbia precludes such from being worked by the dredge miner. For, according to it, a lease gives the right to work in a river only below low-water mark.

In New Zealand, alluvial deposits extend into the banks for acres, and miners are allowed to work the banks as far as they find them profitable.

True bed rock is seldom seen in the Fraser River. In most places the bottom of the old valley is below the present river level.

The formation at Boston Bar is of a slaty and schistose

character closely resembling the Cambrian, but probably of later date. Similar rocks occur at Leech River, Vancouver Island. In each case the slates contain gold-bearing quartz veins. To the degradation of large areas of these slates, the placer gold is probably due.

The present law for dredge mining in British Columbia is drawn so as to protect the placer mining along the banks of the various streams. According to this law a lease conveys the privilege of working material in the bed of a stream from bank to bank, below low-water mark.

Leases are granted by the government at \$10 per mile; and five miles of a river bed may be taken up by a lessee each year. Lessees must enter into a contract to expend not less than \$1,000 per year on the territory occupied by each lease. These lessees must be either miners or joint stock companies holding a free miner's license. Every person over 18 years, regardless of nationality, is entitled to a free miner's license on the payment of \$5 per annum.

Up to the present, dredging in British Columbia has been almost entirely confined to the Fraser River. The yield of placer gold from portions of the Thompson, North Thompson, Columbia, and other rivers on the mainland, as well as from Leech and Sooke rivers, on Vancouver Island, will probably attract the attention of dredging miners to the advisability of prospecting the beds of these streams to ascertain whether the conditions are favorable for dredging. In the foregoing estimate of likely localities, no mention has been made of the more northerly section of the Province, including the Cassiar, Omineca, and Atlin mining districts. So far as we know, no attempts have been made to discover whether the streams in these districts are favorable to this mode of mining.

Undoubtedly, if the companies which are at present using this method of winning gold from the bed of the Fraser demonstrate that the business is profitable there will be no lack of others to embark on a like enterprise.

Considering that there is hardly a river in British Columbia which does not show colors of gold, the field for the industry appears large. The time is not far distant, we may assure ourselves, when dredge mining will be one of the most profitable industries of the Province.

TRANSPORTATION ON INCLINES.

Methods of Getting Coal Down the Mountain From Mine to Tiptle in West Virginia.

Written for MINES AND MINERALS, by Edward H. Cox, C. E.

One of the first questions which confronts the coal operator who contemplates opening a mine in certain portions of West Virginia, is what method he had best adopt to get his coal from the mine up in the mountain down to his tiptle in the valley. Of course the question of power does not enter into the problem, as the weight of the loaded cars going down brings the empties back.

These inclines are laid usually double track or three rail with a passing switch at the middle. Of course the former makes the first cost higher but gives the advantage of a straight track from top to bottom, which is of course, better, making less liability of cars getting off the track.

The next consideration is whether to use drums or sheave wheels, what kind, and their location.

The drums are located at the top of the incline, and usually directly above or below the track, and are of two kinds, straight and geared. The former consists of one drum with one rope winding on from above and one from below, and should have a brake band on each and operated by separate levers, the second one to be used in emergency only, in case the other one breaks. The latter consists of two drums geared, one being set ahead of the other.

With this style of drum both ropes wind on the same way, which under some circumstances is a great advantage, the drums turning in opposite directions.

For a long incline, making speed an essential consideration, the drums should be of large diameter, 10 or 12 feet. These drums should be lined on the outside with wood, as it is easier on the rope than iron, but at the same time it should be well seasoned hard wood so as not to shrink after being put on, and so the rope will not cut into it.

If sheave wheels are used, they may be either single or double. If single, there is a spiral groove passing around the wheel allowing the rope to make three or four turns, and the friction of the rope on the wheel controls the rope when the brake is applied. The single wheel may be either horizontal or vertical or inclined.

If double sheave wheels are used the rope passes around both

in the shape of the figure 8, in some instances making three or four laps, sometimes only one. These may be set on line with the incline or off to one side, the rope passing around a sheave wheel on line with the incline. The sheave system has the advantage of being cheaper in itself and requiring less rope and less space than the drum, but it is much harder on the rope for the reason that when the brake is applied there is a tendency for the rope to slip on the sheaves, causing wear. The sheave is also open to the objection that in wet, snowy, or icy weather, the rope sometimes slips so badly as to be beyond control, or making it necessary to sand the rope or sheaves. The drum also has the advantage that although it requires more rope, if a few extra laps of each rope are left on the drum it allows of cutting some of the lower end of each rope as it wears out, the lower end always wearing out the faster.

The next consideration is whether to use a monitor or to run the loaded mine cars down the hill, and if the latter, how many to the trip, and whether to use a chain and coupling or to use a barney, sometimes called a dummy or bull. The monitor is an iron car of 6 or 8 tons capacity, and is uncoupled neither at the top nor bottom. When it is used, the mine cars are dumped into a large bin at the top of the incline, and the monitor is loaded under this bin and is dumped into the railroad car at the bottom of the incline. This has the advantage of avoiding coupling and uncoupling but possesses the disadvantage of necessitating dumping the coal twice, which of course causes more breakage than if only dumped once. If the miner is paid by weight, the coal must be weighed at the top before it is dumped into the monitor.

If the chain and coupling are used, the cars are coupled to the rope at the top, and if the incline is short, not over 200 or 300 feet, one car is usually let down at a time, and this is sometimes dumped without uncoupling, which is, under most circumstances, an advantage. If, however, the incline is long, time is saved by running two or three cars to the trip and uncoupling at the bottom, having an extra trip on the tippie which will be ready to couple to as soon as the trip lands.

If the barney is used, it does away with coupling at both top and bottom, as the barney runs in front of the cars going down, on a narrower track, thus holding them back, and at the bottom runs into a pit, allowing the mine cars to pass over it, and the empty car or cars are then pushed over the barney hole and the barney pulls them up the hill from behind.

The writer does not advocate the use of barneys on a steep incline or one with a sharp incline at the bottom, as there is so much liability of empty cars getting off the track and if they do they are very liable to turn around and slide back down, as they are pushed from behind by the barney and not coupled to it or the rope. The use of the barney requires a double track from top to bottom, and unless the barney with adjustable double-grooved wheels is used, it requires an extra double track for the barney, but with the adjustable wheels it requires only a short piece of barney track at the bottom, so that the first cost of equipment is higher for barneys.

Each of these methods has its advantages and disadvantages, and the writer does not advocate any particular one, as it usually depends on natural conditions and the details of the results desired which will fill the bill the best.

One thing, however, that is desirable is to have the incline of uniform grade or tending to a concave, as under these circumstances there is much less wear on the cable and the trip is always in sight of the drum runner. Every hump or knuckle in the track hides the trip from the drum runner's view, and makes the rollers at such places hard to keep in place and in shape on account of the pressure on them, and hence makes more wear on the rope.

Another system in use in a few places, and destined, the writer believes, to be used much more where the grade is steep enough, but not too steep, is a long chute from top to bottom into which the mine cars are dumped at the top, and which is dumped directly into the railroad cars at the bottom. About 30° from horizontal is a very good grade for a chute for most coals. If the coal runs too fast, heavy check doors hinged at the top can be placed in the chute at intervals. This system has the advantage, that if there are no railroad cars at the mine the chute can be filled up and the cars loaded from it when they get there.

On account of the annoyance from rats about many mine barns, particularly underground, the following from *Electricity*, New York, is of interest: "When I was in Chicago for a few weeks last summer," said a well known electrical engineer, recently, "the office building I was in was infested with rats. At my suggestion the owner of the premises placed two electric wires of opposite polarity across the rat holes in the basement in such a position that a rat must touch both in coming out. Some were shocked, but most of them were killed, and the place was soon entirely free from the pests."

WELSH COKE OVENS.

A Description of a Form of Oven Used in West Virginia in Place of Beehive Ovens.

The beehive coke oven is in such general use that the other forms, excepting the by-product types, are usually lost sight of and they are seldom mentioned.

It is probably not known even to many coke producers that the Welsh type of oven is used at a number of plants in West Virginia. This is an old form of oven which was originally designed to reduce the cost of coke drawing from the beehive oven by the substitution of a mechanical drawer for hand drawing.

The oven consists of an arched chamber, rectangular in shape, having one end walled up and the other or front end closed by doors or by a wall of luted firebrick. The gases escape by a chimney located at the rear end of the oven.

A characteristic feature of these ovens is the drag for drawing the coke from the oven. This consists of an iron bar laid on the oven bottom, and having a cross end-piece at its inner end. The charge of coal is laid on top of the drag, and after the coking has been finished it is drawn out by a windlass or by an engine.

The modification of the Welsh oven as used at the Red Ash Mines, West Virginia, has been described for MINES AND MINERALS by Mr. F. Howald, E. M., general manager of the Red Ash Coal Co., as follows: Our plant consists of 80 Welsh coke ovens. They are rectangular in shape, 15 feet deep in the clear, 6 feet wide at back,

and 6 feet 4 inches wide at front. They are arched with a cylindrical arch of 42-inch radius, 12-inch arch brick being used. From the floor at front to spring of arch, distance is 48 inches, and to crown of arch the height is 5 feet 10 inches. Floor is laid with 12" x 12" x 4" blocks, and is 4 inches lower at front than at back. The division walls between ovens are 27 inches at back and 23 inches at front. Center of charging hole is 8 feet 11 inches from front. The products of combustion pass through openings in the back wall either into flue or into short chimneys. At the front the opening of oven is reduced to a height of 4 feet 8 inches by an arch of 4' 10" radius laid up with arch brick 16 inches deep and 12 inches wide. Over this front arch, wall is laid up with red brick to hold filling over ovens. The opening of oven is closed with double doors hinged at center of division wall. The doors are made of firebrick blocks 6 inches thick bolted to angle iron frame. A space is left between the doors for leveling, which is afterwards closed with brick and daubed. The accompanying sketch of right and left door of adjoining ovens shows skeleton of frame and how the doors are hinged.

After an oven is drawn, and before it is again charged, a drag 5 feet long, cut from 60-pound T rail is laid across back of oven. To the drag is attached a drawbar extending to front of oven. The ovens are drawn by means of a $\frac{5}{8}$ -inch wire rope, two blocks, and a grip, the power being supplied by a $\frac{3}{4}$ -inch endless wire rope running along front of coke wharf.

The heat from 40 of these ovens, instead of being wasted, is carried into a firebrick flue of approximately 15 square feet area running back of the ovens, which carries the heat under a 300-horsepower Stirling boiler.

The oven is, of course, a very old type, first used in Wales, and is, I believe, still in use there.

COPPER DEPOSITS

Of the Ajo Basin, Gila Basin, Arizona—The Large Amount of Mineral and Difficulties of Exploiting.

A Description of the Country and Its Facilities in Regard to the Supply of Fuel and Water and Timber Necessary to Operate the Mines in That Region.

Written for MINES AND MINERALS, by Prof. Arthur Lakes.

To one visiting for the first time a new or little known region, the charm of novelty is great. People, trees, flowers, birds, and beasts all claim their share of interest. Nor is the sudden change of scene less noticeable than that of climate. A week ago we were hugging a stove in a miner's cabin in the Gunnison Mountains of Colorado, after a tramp knee deep through the snow; today we find ourselves in our shirt sleeves chasing the shadow of a lone tree, or a great rock in the warm deserts of Arizona.

Such was our experience as after a tedious day and night journey we woke up on what seemed a calm spring or summer morning in the month of February, at Gila Bend, in a spacious adobe room, adjoining the stable of the Gila coach which was being hitched up outside to carry us bright and early over the Gila Desert to the Ajo copper basin, some 50 miles distant. We were advised of our semitropical surroundings by a palmetto growing in the yard opposite our window, whilst across the road, over at the railway station, was a garden full of strange cacti, aloes, and yuccas, plants we were to see later on a much larger scale in their native habitat in the Gila Desert.

We were on a flat sandy plain 50 to 100 miles in length and breadth, seemingly encircled by mountains of the wildest and

driver informed me, it is dangerous to ride or drive, for fear of the horses stepping on the reptiles.

Of birds we saw few; amongst them that singular long, very thin bird called the road runner, who with his long beak is a formidable enemy to the various reptiles. Flocks of California quail, with their pretty little parasol top knots, are very numerous, and a species of small humming bird swarms among the cactus and other desert flowers.

Despite the general aridity there are evidences of not infrequent very violent rains or cloud bursts which, at certain seasons, turn portions of the country into a sandy, but short-lived lake, and sweep through the dry watercourses with terrific force. The surface water is soon gone and absorbed by the thirsty sand, but by digging a few feet, a well soon discovers a fair amount of water.

We took special notice of these facts, because the water and wood problems are supposed to be the most formidable obstacles in the way of Arizona mining.

Timber and Fuel Facilities.—Along these dry watercourses, or arroyos, is a very peculiar arborescent vegetation. These bush-like trees are unlike any we have seen elsewhere. The commonest and perhaps the most singular is a tree from 15 to 20 feet high, called the "Palo Verde," or green tree, and it is the most emphatically green tree at all seasons of the year we have ever seen. The bark on the trunk which may be 6 inches to a foot or more thick, is as green and smooth as a green apple, or as if it had been fresh painted; the branches and twigs are all of the same tint, and the foliage is of a seaweedy, or plumose character. Like all the vegetation of this desert it is armed with formidable thorns. The wood is soft and is much bored into by woodpeckers and wood-boring worms, which causes it to decay. It makes a fair fuel for mining purposes, and cordwood can be cut off it with diameters from 6 to 10 inches. Besides this is the mesquite tree, a species of Mimosa some 15 to 20 feet high, with trunk 6 to 10 inches diameter, and another tree about the same size, whose

THE AJO CRATER BASIN LOOKING SOUTH FROM DIORITE PEAK.

ruggedest outlines. The plain was evidently the bed of a great lake or sea, extending for hundreds of miles north and west into Northern Arizona and Southern California, about 150 miles distant, of which it was probably once an extension. The mountains, all of them volcanic, though seeming to surround the plain as by an impassable barrier, are in reality more like a collection, or archipelago, of islands, amongst which, by innumerable passages, the "prairie schooner" can sail anywhere at will.

About four miles north of the station, a long line of cottonwoods marks the bending course of the Gila River, one of the few living rivers of this arid zone. Even of this, a large proportion of the water sinks into the sand, and throughout Arizona, often a better river may be found by sinking a few feet below the dry bed than the one that flows in places above that bed.

After breakfast at the Mexican adobe hotel, our coach started southward in the pleasant early morning to the Ajo mines. Now, as we entered the desert the barren adobe ground was strewn with volcanic pebbles, the soil unbaked, parched, and cracked was scantily clothed, not with the usual sage brush, but with a small species of bush Mimosa, of a brownish-green tint, with small yellow flowers, called the mesquite.

At the roots of these bushes, where the soil accumulates and where there may be a little shadow and moisture, numerous small holes are bored, tenanted by small chipmunks, who scamper along with bushy tails erect. Some of these holes are the abodes of rattlesnakes, and others of that strange, sluggish, repulsive looking pink and black lizard known as the Gila monster, whose bite is said to be as deadly as that of the rattlesnake, which often here attains a size of 4 to 6 feet in length.

Over rocks and sand glide tiny, little, swift, harmless lizards, flashing hither and thither like a streak of lightning.

In summer, the heat is so great that even the rattlesnakes do not emerge from their holes till after dark, and then, as my

species we do not know, called an "iron wood," or "mahogany." The wood of these trees is hard and not unlike mahogany or boxwood, and makes a very hot fire. For small work in mining these trees might also be used. These are the main staples of fuel in this otherwise treeless region, and despite their comparatively dwarf size, their abundance makes them a very fair substitute as a fuel for the usual forest trees of more favored and wooded regions.

But by far the most striking and peculiar vegetation is that of the "cactus" family which in this region assumes the most grotesque and extraordinary forms, and attains to the most gigantic proportions. Most remarkable of all is the Suwarrow (saguaro), or giant cactus (*cereus giganteus*). When first we strike the desert we fancy it is dotted over with telegraph poles, until we approach one of them, and find it to be a beautiful fluted column of green cactus fiber, 20 to 30 feet high, and 1 foot to 2 feet in diameter. About two-thirds of the way up the column, or 15 feet from the base, one, two, three or more great horn-like branches start from the trunk, giving the cactus the appearance of a huge candelabra. The tips of these horns as well as the top of the column are at certain seasons crowned with beautiful cream-colored cactus flowers. Passing through groves and colonnades of these extraordinary forms of vegetation, together with those of no less grotesque but humbler shapes, we fancy ourselves back in the old Carboniferous period, among its strange forests of "lepidodendra," gigantic reeds, and mosses. As a young plant (according to the botanist Engelman) 5 or 6 inches high, may be 10 years old, we may form some idea of how old a monster 25 to 50 feet high might be. Some of these are broken and in various stages of decay, showing a curious inner skeleton of long, tough, lath-like fibers, which as they are used both for fuel and for building purposes, or lining of adobe houses by the natives, may also be included amongst the fuel and timber resources of the Gila Desert.

The flowers have a long tube, and are 5 to 6 inches long and 3 to 4 inches diameter. The petals are a light cream color. The fruit is pear-shaped, 3 or 4 inches long. The flowers are open day and night. This cactus belongs to the *Cereus* family, and is called by botanists the *Lepidocereus Giganteus*.

There is another *Cereus* called by the natives Pitahaya pronounced "choya," which is smaller, and has numerous branches thickly covered with yellow spines, at a distance looking like yellow wool. The dead trunk or branch fiber of this shows, when dry, an elegant reticulated pattern.

A very formidable looking cactus about the size of a small barrel is covered with the strongest and most cruelly curved fish-hook spines it is possible to imagine. Its purpose in life seems to be "to have and to hold."

Another singular plant like a lot of tall whiplashes, tipped with tiny red flags, is called the *Ocotilla*, pronounced *Ocatēca*. When overthrown and lying prone on the ground, the numerous long arms all spreading from the same root, remind us forcibly of an octopus, or devil fish. This also in a minor way is used for fuel, in fact, everything that will burn is so used, and most of these plants produce an exceedingly hot fire.

The Indians, in war time, used to make a curious use of the giant cacti. They ignited the fine spines which line the edges of the fluted columns, and in a moment a column of flame and smoke rose to the top and into the sky, and so they signaled to one another.

Midway to the Ajo basin we passed through the eroded crater of a big extinct volcano. The walls were of black basaltic rock; the bottom of the crater might be a mile or two in diameter; everywhere great rugged masses of black lava were piled one upon another, giving the place a most wierd, sombre, and inferno-like aspect. High up amongst the black walls, in crevices of the

north end in a very tall peak of mica diorite, a rock much resembling granite; the remainder of the northwest wall appears to be formed of dark basic varieties of diorite, and of diorite breccia. These walls are traversed by narrow dikes of dark diorite having a general easterly direction. Two of these dikes, close together and parallel, must once have formed the northeastern portion of the wall of the crater, which at present is an open gap to the basin, the dikes having been eroded down nearly to the basin level. The eastern wall is composed of diorite breccia, and the southern of an exceedingly coarse volcanic agglomerate; the fragments of rock in this cemented with an adobe sand are often a foot or more in diameter. Right in the center of the basin, and a most conspicuous object especially to the prospector, are two hills about 200 feet high, about 2,000 feet in length, and about 1,000 feet wide at the base. These, from a distance, have a dark rusty-brown color, and nearer, appear here and there heavily stained with bright green carbonate of copper. This mountain is justly named Copper Mt., as we shall have reason to explain later.

On the north end of it, near an arroyo, the works and mines of the St. Louis Co. are established, and at the south end of it, on a little knoll, are the ruins of an old Spanish fort, built to protect a mine close to it as well as a rude smelting furnace, the ruins of which still remain. The walls of these buildings are built of the gay green, blue, and red rocks derived from the copper mines; in these, sometimes occur specimens of native copper, which appear to have attracted the Spaniards and for which they mostly mined.

Tradition has it that the Spaniards were massacred by the Apaches; there are the remains of an old cannon near the spot which seems to have burst in an attempt to fire it.

The flat part of the basin, on the east, has several prospect holes, or young mines on it, which show on the surface a great

THE AJO BASIN COPPER FIELD LOOKING EAST.

rock, towered the lofty fluted columns of the giant cacti, apparently without earth or moisture.

As evening drew on, we approached that most important of all things in the desert, a well of good water, 50 feet deep, yielding about 2,000 gallons daily, around which was a rude cattle corral, built of the gnarled branches and trunks of the desert vegetation. Close to it some Pappago Indians were encamped in their rude "wickups." These Indians do considerable dry placer mining in the dry and sandy arroyos. They dig a hole through the loose gravel down to bed rock and sift the gravel against a rude wire screen, collecting the finer particles in a wooden dish or batea, and winnow off the fine sand with their breath, until the particles of gold appear.

As evening closed in we drove up the dry bed of an arroyo, passing on our way another well much the same as the last, and a small cattle corral. This well, pumped to the surface by a small windmill, yielded about 2,000 gallons daily of good drinking water. A little farther on we passed a long 2-inch pipe, which brings water from a well to the St. Louis Co.'s stamp mill, and is stored in a reservoir, holding 5,000 gallons close to their works.

As darkness drew on we found ourselves entering among the walls of the great Ajo volcanic crater, and no music could be pleasanter to us after our 50 miles lonely desert drive than the dropping of the stamps of the 10-stamp mill, or a pleasanter sight to our weary eyes than the light in the window of Mr. Shotwell's hospitable cabin.

Next morning we were awakened early by the pounding stamps of the mill, and went out to view the basin. For this purpose we climbed a tall hill near the center of it. Ajo basin occupies a much eroded crater of an ancient volcano. The basin may be from two to three miles long by two miles wide. A rudely outlined wall of hills and ridges surrounds it. The bottom of the basin is comparatively flat. The steepest walls are to the northwest, where they rise from 300 to 1,000 feet, culminating on the

deal of green copper carbonate, and with depth, solid bodies of bornite and copper glance. Nearly all these assay high, from 6 to 60 or 70 per cent. copper.

Our interest, as naturally that of any one first entering the basin, was centered on Copper Mt. and its extraordinary oxidized appearance, and we hastened to examine it. We found the country rock composing this mountain to be a species of porphyritic diorite, or porphyrite, composed principally of plagioclase feldspar and crystals of hornblende.

The rock showed generally signs of decomposition; the mountain is traversed in an east and west direction by a series of parallel cleavage planes. Some of these are occupied by narrow quartz veins of lenticular shape.

Along some of the cleavage planes there were strong stains of green carbonate of copper, and open cuts that had been made on these showed rich impregnation of the rock to as great a depth as the cut extended, usually not over 50 feet. Amongst these green stains were streaks of dark copper glance running very high in red copper, also some red oxide of copper or cuprite. In numerous places all over the mountain bright green stains issued from the rocks. But the most remarkable feature appeared when we attempted to make a rough sampling of the mountain. To do this we began to break off small pieces of the brown oxidized rock at intervals of a few feet, when, to our astonishment, we found that every fragment of the rock in every part of the mountain immediately below the veneer of brown oxide showed a strong stain or impregnation of copper carbonate which appeared to descend a few inches at least into the rock. We came to the conclusion that the whole surface of the mountain, from end to end, was impregnated with green carbonate of copper, to what depth we could not tell, but we can give our readers a just idea of the mountain by saying that, in a picture, if we were to paint it all bright Paris green instead of brown, we should only represent it as it really is a few inches below the surface. Below the brown

thin oxidized veneer or skin the general rock from the green stain appears to pass down into a partially oxidized diorite with spots, patches, and grains of copper glance and bornite, with some chalcopyrite.

It would seem as if these metals had in part replaced the dark constituents of the rock such as hornblende. So with depth the ore rock, as that from the St. Louis mine, resembles a decomposed granite, the black minerals instead of hornblende or mica,

OLD SPANISH FORT AND SMELTING WORKS.

being often copper glance or bornite, somewhat as telluride minerals replace the hornblende and mica of the decomposed granite of the Independence mine at Cripple Creek, Colorado.

Copper Mt., taking it as a whole, is certainly the most wonderful impregnation of copper minerals we have ever seen. To what depth this impregnation goes, or what values, or proportion of values with depth form the bulk of this remarkable mountain, it would be premature to form an opinion until deeper developments have been made.

Projected Mode of Development.—The only way to prove up the mountain is to open a tunnel from its base clear through its length of about 2,000 feet from end to end, and if necessary one right across its width of 1,000 feet, and from the center, where these meet, to make an upraise to the surface, and a downcast below it. The longitudinal tunnel N and S would cut through all the east and west transverse cleavage planes, in which we have some reason to expect the main zones of impregnation will be concentrated. A depth of at least 200 feet would also, by this means, be gained under the mountain sufficient to show up the surface character of the hill. As this tunnel would start at water level, it would show above it what the character and values of the oxidized zone are likely to be. To show the nature of the unoxidized or sulphide zone, below water level, the shaft proposed in the center of the mountain will have to be carried down a hundred feet or more.

A remarkable feature of Copper Mt. is its minutely and intensely fractured condition; every foot of diorite is reticulated with minute cracks which are often cemented together by copper solutions. It would seem as if the mountain had been, in this respect, like a huge porous sponge readily penetrated and soaked by the copper solutions ascending from below. Throughout the whole section we could not see anything we could positively call a true fissure in the ordinarily accepted sense, such as a vein of quartz, or vein matter between defined walls.

What were locally called veins, appeared to us to be merely zones of exceptionally strong impregnation, only partially limited or defined by the natural cleavage or joint planes of the country rock.

The probable conditions of the mountain, such as will be revealed by deep exploitation, will, we think, be (1) a thin surface veneer of iron oxide, only a few inches deep. (2) Below this a zone, more or less deep, of copper carbonates mingled with streaks of iron and copper oxide and copper glance and a little bornite. (3) A final zone of bornite and chalcopyrite which will be the permanent condition of the ore with depth.

Lenses of rich ore are liable to occur anywhere. The assays from this basin are no less remarkable than the wonderful extent of the impregnations; they generally run all the way from 3 to 6 to 30 per cent. copper, whilst richer samples will yield 60 and 70 per cent. The assays from the concentrates at the St. Louis mill, on 12 tons concentrated into one, average about 60 per cent. copper, with 1 to 2 ounces gold; and this is from the deepest shaft in the basin, which is not over 100 feet deep.

Mines and Mills.—The developments on the basin may be all called prospects, as there are none much over 100 feet in depth. The principal of these is that of the St. Louis Co. at the north extremity of Copper Mt. Their mine is down about 100 feet; they have passed down through a rich zone of sulphurets and bornite and glance, which continue as impregnations of the rock to the bottom of the shaft, bounded by cleavage planes. In these cleavage planes are narrow lenses of ore of bornite, iron, and

chalcopyrite, rich in copper, averaging 31 per cent. The ore now brought to the surface is a decomposed diorite speckled with bornite and glance. The concentrates run about 65 per cent. copper with 1 to 2 ounces gold. This they concentrate in the adjoining 10-stamp mill.

Mode of Economizing Water.—Both the mine water, which came in a fair stream at 75 feet, yielding about 1,000 gallons daily, and that from a well about half a mile distant, brought to a reservoir near the mine by pipe line, are utilized to drive the 10 stamps, each of which are 900 pounds weight, with two Woodbury tables immediately below them. The water, after passing over the tables, goes into two or three tanks situated just below the mill, each tank having a capacity of 4,500 gallons. In these the tailings settle and pass to waste down the arroyo, and the purified water is pumped up into three similar tanks just above the mill, in one of which is also a condenser, formed of layers of worm-like horizontal pipes condensing the steam from the boiler and engine.

These pipes are cooled by the water pumped up from the tanks below, and that water, together with the condensed steam water, is again returned by pipes to the mill. It is thus seen that the utmost economy is used with that most precious of all elements in this country, viz., water.

The well feeding the reservoir is 2,500 feet distant, located on the bed of a dry arroyo. It is 55 feet deep, and water begins to come in at 25 feet; it yields about 1,000 gallons daily. The water is pumped from the well to the reservoir through a 2-inch pipe. This reservoir has a capacity of 4,500 gallons, which is sufficient to reduce 8 to 10 tons of ore daily.

The water question is the most serious one in this district. There can be little doubt as to the vast quantity of ore of this extraordinary basin. The question is, what to do with it. The superficial investigator who comes in one day and goes out the next is inclined to jump to the conclusion "Lots of copper, but no wood, no water, therefore no good at the present distance from railroads."

But not so fast, my friend. Look around you at that brown haze over the prairie, extending for miles as far as the eye can reach. That is all prairie timber such as I have described, and hundreds and thousands of cords of that wood can be laid down at your mill at from \$2 to \$3 per cord by the Mexicans for at least some years to come, till a railway is built, as seems probable, from Gila Bend to the Gulf of California, over a country for the most part as level as a billiard table, when bigger timber can, if need be, be brought in, and ores, if necessary, be transported out to a suitable place for milling, as at Gila Bend, near the Gila River. So much for the fuel and wood question, now for the water.

I have before alluded to the great underground rivers or underground drainage system of Arizona. At Deming I saw a windmill in every cottage garden, and these all draw ample water for household and irrigation purposes from the arid prairie at a depth of 50 feet.

The whole country, as we have observed, from Gila Bend to Ajo basin, 50 miles, is traversed by a network of seemingly dry arroyos. That these contain moisture below, is shown by the dense growth of Palo Verde and other succulent trees along their courses, and we believe almost everywhere in these a well would find water at a depth not often exceeding 50 feet. These dry arroyos are particularly plentiful in the Ajo crater basin, and

ST. LOUIS COPPER MINE AND STAMP MILL.
T, T, Tanks; W, Woodpile; M, Mine.

every mine that has gone down to 70 or 100 feet has encountered more or less water.

Only two wells have, so far, been sunk in the basin; one on a ranch and the other for the St. Louis reservoir; both of these yield about 2,000 gallons each daily. One of these is sufficient to keep the 10 stamps of the St. Louis mill going 10 hours daily. It appears to us that we have only to multiply wells and to increase the size of reservoirs to supply water sufficient to run stamp mills of 20 stamps or more, 24 hours daily throughout the year.

The extreme porosity of the Ajo basin rock, and the fact that the crater appears to be a sort of sink, or center for the drainage of the immediate region, would argue in favor of the basin holding, below its surface, considerable underground water. At Gila Bend is ample water in the river, both above and below, for a mill of any capacity. Should water or wood fail in time in the Ajo basin, the problem of milling could be solved by a small narrow-gauge line to Gila Bend, by the erection of a large mill there, and by the transportation of the crude ore from the basin.

At present, only the richest ore or concentrates can be transported to the railroad and thence to works for final treatment.

Geology of the Basin and Its Ore Deposits.—The basin appears to be an old and much eroded volcanic crater, one of those old craters of which there seem numbers in this moon-like region.

Erosion may have cut it down nearly to its roots, to the deep laccolitic reservoir from which the main eruptions proceeded, or at any rate to the plug, or stopper, filling the throat of the volcano. The eruption appears to have been at one time more or less explosive, as large portions of its walls are formed of fragmental material, consolidated into a breccia, or into an exceedingly coarse mud-flow agglomerate, such as appears notably at the south end. Later eruptions penetrated the older ones of a more basic variety, as shown by the narrow parallel dikes traversing the northwest wall.

The prevailing rock appears to be of the diorite family with several varieties; some porphyritic, others micaceous like granite, and others resembling andesite and basalt or dolerite.

The central core of the basin represented by Copper Mt. appears to be of porphyritic diorite or porphyrite.

The explosive character of the eruption, or the general earthquake shaking up of the interior of the crater may account for the intensely fractured character of the rock of the Copper Mt. area. The various cleavage planes and so-called fissure veins may be due, also, to these disturbances or to cooling and contraction.

After the eruptions, the crater basin was the scene of solfataric, or hot-spring and fumarole action, and the ascent of various gases and heated waters, the latter charged with silicious and metallic solutions, the copper element apparently prevailing. These charged the much-shattered and porous rocks, thoroughly impregnating them, and in places deposited solid bodies of ore in cleavage planes or other openings. The whole basin may have been once, as suggested by Professor Eames, "a boiling pool, the waters of which washed the edges of the basin as well as acted upon the deep-seated materials, dissolving out the copper from the ore and again combining with carbonic-acid gas gave rise to the coloring matter of the rocks throughout the whole basin, again depositing in their interstices the materials it had dissolved, but still leaving the main body of ore in the veins."

As the solutions forming the impregnations doubtless came from below, the Plutonic deep-seated character of the rock, the deep-seated plug, or reservoir, of the crater, as well as the fractures along the path of dikes offer strong probabilities for continuity and permanence of the ore bodies with depth, and the probability of finding valuable concentrations of ore below, of which the painted rocks on the surface are as the flower is to the fruit.

There seem great possibilities for this truly remarkable basin and its wonderful ore deposits and impregnations.

Annual Outing of the Engineering Association of the South.

On Friday, June 15, the association held its annual outing at Mt. Pleasant, Tenn. Through the kindness of President M. H. Smith, of the L. & N. R. Co., a special coach was placed at the disposal of the association. A large number of members, their friends, together with their wives and sweethearts made up the party. The run to Mt. Pleasant from Nashville was highly enjoyable, as the road traverses the most beautiful farming section of Middle Tennessee, and everywhere waving wheat and growing corn gave a glad welcome. At Mt. Pleasant the local committee on entertainment gave a hearty welcome and throughout the day exerted themselves to make every one have the most delightful time.

Mt. Pleasant, which only a few years ago was a small way station, has now suddenly sprung into importance as a great phosphate center, and its population has gone into the thousands. It has the proud distinction of shipping 100 cars per day. The industry at this point has grown marvelously, and the extensive and well equipped plants now in operation were a revelation to many of the members. The rock in this section being of exceptionally high grade much of it is exported.

At the plant of the Tennessee Phosphate Co. the party was given quite a surprise, the management having prepared delightful liquid refreshments, which served as an admirable inspiration after the fatigue of the morning. After the plants of this com-

pany were thoroughly inspected the special was run up the Mt. Pleasant Southern Railroad to the plant of the American Phosphate Co. The hour for dinner having arrived, the party left the train for a more pleasant spot. Tables had been prepared under wide spreading boughs on the banks of the Big Bigby Creek, and here a most bountiful supply of tempting eatables was spread, and needless to add this feature of the programme was slighted by no one. The ladies who have always so bountifully attended to this part of the programme seemed to have made a special effort for this occasion, and rarely is it the good fortune of one to be a participant in such a repast.

After dinner a short business session was held, and in the absence of President Geddes, Mr. John B. Atkinson, of Earlington, Ky., was called to the chair. Ballots for membership were canvassed and resulted in the election of the 15 applicants. Applications for membership were received from two gentlemen. Resignation of Mr. Howard White, Jr. was accepted. Resolutions thanking the following parties were passed: President M. H. Smith, of the L. & N. R. R., for the transportation of the party, and other officials of said road who contributed largely to the success of the occasion; the ladies; the committee on arrangements and the local committee; and the various phosphate companies. The business session then adjourned.

Under the guidance of Messrs. H. D. Ruhm, general manager, and G. F. Blackie, superintendent, of the American Phosphate Co., an inspection of their recently completed plant was made, and it was found to be a most thoroughly equipped and neatly finished one. Much credit is due Messrs. Ruhm and Blackie who were the designers and constructors. The special then made a run to the Bluegrass Phosphate Co.'s and International Phosphate Co.'s works, after inspecting which, the return trip to Nashville was begun.

The day was ideal; the company congenial; the works interesting and instructive; and in all it was one of the best outings the association has yet held.

H. M. JONES, Secretary.

Otis Feedwater Heater.

The Otis tubular feedwater heater and purifier, illustrated by the cut, is made by the Stewart Heater Co., of Buffalo, N. Y. It consists of a body or shell which is made of boiler iron or steel, on top of which is riveted a heavy cast-iron ring which has a projecting rim cast upon its outer surface, forming a flange to which the tube sheet and top dividing plate are attached by a single row of bolts. The lower end of the shell is riveted to a conical bottom, which is supported by legs as shown.

The exhaust steam enters the heater at the top, as shown in cut, passes down one section of tubes into the enlarged space of the water and oil catcher, where the water of condensation and oil are separated, and the exhaust steam then passes up through the other section of tubes, thus passing twice through the entire length of the heater, heating the feedwater to the boiling point. The exhaust steam can then be used for other purposes or exhausted into the atmosphere.

The water enters the heater near the bottom, and passing upwards in contact with the heated tubes, gradually becomes thoroughly heated, and is discharged as near the top as practicable, so as to avoid carrying the scum that is on the surface of the water into the boiler.

With this device the feedwater is thoroughly heated by the exhaust steam before it enters the boiler. Mud and sediment are separated from the feedwater and are removed quickly and easily from the heater, which also collects the scum from the surface, the water collecting and carrying off the condensation of oil from the exhaust. The company claims that these heaters will heat the feedwater to a boiling point with the exhaust steam without causing any back pressure, that all impurities are separated from the water, that the heater will not get fouled with scale, that it separates and carries off odor of condensation, that it saves oil and carries off the steam, and that a saving of 15 to 25 per cent. is effected over the use of an injector.

An Automatic Lubricator.

The lubricator here shown is to be attached to any reciprocating or oscillating parts of engines or machinery requiring constant and reliable lubrication, as the cross-heads, connecting-rods, eccentric straps, etc., of engines, pumps, air compressors, etc. As it feeds grease instead of oil, it may be attached in any position desired, feeding vertically upward or downward, horizontally, or at any angle desired. It feeds only when the part to which it is attached is in motion.

The base of the lubricator is screwed firmly into the part to be lubricated in the usual way. The body is attached to the base by the union nut or enlarged ring at the top. When this is unscrewed the upper part is all taken off together, the barrel is filled with a charge of grease and returned and securely clamped in the position again by the union nut. The feeding is accomplished by the pressure of the piston, and this pressure is applied by the vibrations of the pendulum seen in the front. By the adjustment of the stop-screws at the side, the pawl attached to the pendulum may be made to take from one to six or more teeth of the ratchet wheel for each vibration. On the ratchet-wheel shaft is a worm which meshes into the large worm wheel at the top. The central screw or spindle is splined, and revolves with this wheel at the same time that it travels downward by the operation of its thread in the central nut, which is screwed into the bracket or guide at the top. The feeding goes on, if the vibrations continue, until the piston reaches the bottom and the grease is all expelled. To raise the piston for refilling the barrel, the

central nut, which has a milled and notched head, is unscrewed from the bracket, the piston is pulled up, the nut is whirled down the screw by hand, and screwed tight in its place again. The ratchet wheel may be pulled around by hand until the slack is taken up and feed is fully established, and if at any time it is desirable to feed in an extra quantity of grease, this also may be done by turning the ratchet wheel. The lubricator may be made of any size and for any rate of feed desired. The one here shown will hold about 14 cubic inches, or somewhat less than half a pint of grease. The ratchet wheel has 100 teeth, the spindle has 125 teeth, the central

spindle is 24 threads to the inch, and the travel of the piston is $3\frac{1}{4}$ inches. If, then, the pendulum is set to take two teeth of the ratchet wheel for each stroke, the number of strokes required to empty the barrel will be: $(100 \div 2) \times 125 \times 24 \times 3.5 = 525,000$, and at 200 strokes per minute this would last 2,625 minutes, or say 45 hours. Any of the usual kinds of grease may be used in the lubricator, and any percentage of pure graphite may be mixed with it. The worm is of steel, and the pawls are of steel hardened, and the wheels are of hard bronze.

The lubricator was designed and patented by C. U. Merrill, of Paterson, N. J., and is made and sold by J. L. Robertson & Sons, Fulton Street, N. Y.

CURRENT MINING DECISIONS.

Prepared for MINES AND MINERALS.

A Location Notice.—A location notice of a mining claim which fails to give the direction of the initial point, or permanent monument to which it is attempted to tie the location, from the point of discovery, is void, under the statutes of Idaho.—*Brown v. Levan* (Idaho) 46 Pac. Rep. 661, affirmed. *Clearwater Short-Line Ry. Co. v. San Garde et al.*, 61 Pac. Rep. (Idaho) 157.

Lien on Mining Plant.—Illuminating oil, mica grease, lubricating oil, and gasoline for fuel used in a mining plant did not enhance the value nor become part of the machinery, and hence were not lienable, within Code Civ. Proc. § 2130, providing that every person furnishing material for any machinery, fixture, or building shall have a lien therefor.—*A. M. Holter Hardware Co. v. Ontario Mining Co. et al.*, 61 Pac. Rep. (Mont.) 8.

Natural Object or Permanent Monument.—A description in a certificate of the location of a mining claim that the mine is located in a certain section on top of the mountain south of Dew Drop Gulch is sufficient, since such gulch is a natural object or permanent monument.—*Duncan v. Fulton et al.*, 61 Pac. Rep. (Col.) 244.

Patented Mine a Natural Monument.—A description in a certificate of the location of a mining claim which locates the mine a certain distance from a patented mine is sufficient, since such patented mine will be presumed to be a natural object or permanent monument, until the contrary appears.—*Duncan v. Fulton et al.*, 61 Pac. Rep. (Col.) 244.

Partition of Surface Land.—The surface of mineral lands may be owned by one person, and the mineral underneath by another, each with an indefeasible title. When so owned, they constitute separate corporeal hereditaments, with all the incidents of separate ownership, and the surface land may be partitioned the same as where there is no mineral under it.—*Smith v. Jones et al.*, 60 Pac. Rep. (Utah) 1104.

Action to Quiet Title to Mineral Land.—In an action to quiet title to mineral land, where a conveyance from the original locators to defendant, under which he claimed, was shown to have been lost, and that he had never read it, it was not prejudicial error to allow him to testify as to when the instrument was made, and when he began work on the claim.—*Simmons v. McCarthy*, 60 Pac. Rep. (Cal.) 1057.

Safe Place to Work.—A mining company, which erects a stull or platform across a narrow and dark fissure in its mine, 70 feet from the bottom, on which its employees are required to work, is bound to the exercise of reasonable care to see that the timbers are of adequate strength and number, and securely fastened, to render it a safe place on which to work.—*Westland v. Gold Coin Mines Co.*, 101 Fed. Rep. (U. S.) 69.

Judgment for Royalties.—Where plaintiff recovers a judgment for the full value of certain coal mined by her lessee under the lease, and it is held, on appeal by the lessee, that she is entitled to recover royalties thereon, plaintiff will be given the option of either remitting so much of the judgment as is in excess of such royalties, or submitting to a new trial.—*Genet v. President, etc.*, of Delaware & Hudson Canal Co., 57 N. E. Rep. (N. Y.) 297.

Meaning of "Reprises" in Lease.—The lessee of coal lands is liable for an assessment for sewer, his covenant being to pay a stipulated rent "clear of and above all taxes and reprises," the word "reprises" meaning such deductions for burdens incident to the land as such as are required to be made from gross income in order to ascertain the clear or net profit.—*President, etc.*, of Delaware & Hudson Canal Co. v. Von Storch, 46 At. Rep. (Pa.) 575.

"Mine Run," Meaning of Term in Lease.—A mining lease stipulating for the payment to the lessor of a royalty of five cents per ton of 2,200 pounds on all lump coal mined, and five cents per ton on all "mine run" coal mined, does not entitle the lessor to a royalty on screenings, consisting of nut and slack coal left after the lump coal is separated therefrom, as the words "mine run" coal mean the coal as it comes from the mines.—*Hardin v. Thompson*, 57 S. W. Rep. (Ky.) 12.

Ambiguous Description.—A deed of mineral land described the tract conveyed as a lot situated in a certain town, county, state, "fronting 25 feet on" a certain road, "extending back east 125 feet, more or less, to the gulch, and lying about 25 or 30 feet from the south side line" of a certain claim. Held, in a suit involving its construction, that the description was not so ambiguous as to authorize the submission of the case to the jury.—*McGuigan v. Hennessy*, 61 Pac. Rep. (Mont.) 1.

Extent of Structure.—Under Hill's Ann. Laws, § 3669, providing that material men shall have liens on any "structure" where a stamp mill and tramway is built from the mill to the mine, the mill, mine, and tramway do not constitute such an entire "structure," so as to invalidate a mechanic's lien filed for material used in erecting the mill and in constructing the tramway, because such lien was not filed against the mine also.—*Watson v. Noonday Min. Co. et al.*, 60 Pac. Rep. (Ore.) 994.

Provision in Lease Regarding Culm.—Defendant leased of plaintiff all the coal contained in or under certain lands, and was to pay for coal mined and taken out, at a certain royalty per ton, on clean, merchantable coal, "exclusive of culm or mine waste which would pass through a one-half inch mesh," and that defendant should pay for 10,000 tons yearly, whether that amount was taken out or not, and interest on sums representing yearly deficiencies below 20,000 tons until that amount was reached. Held, that the provision regarding culm was to be construed as permitting defendant to mine and appropriate culm, it was liable for royalties thereon.—*Genet v. President, etc.*, of Delaware & Hudson Canal Co., 57 N. E. Rep. (N. Y.) 297.

Notes on Scientific Societies and Publications.

For Directory of Mining Societies and Mining Officials, see Advertising Page 61.

The Autumn meeting of the British Iron and Steel Institute will be held at Paris, under the auspices of the Societe d'Encouragement pour l'Industrie Nationale, on Tuesday and Wednesday, September 18 and 19, 1900.

Mr. Henry Chapman, who was honorary secretary at the meetings of the Institute at Paris in 1878 and 1889, has placed his office, 10, Rue Laffitte, at the disposal of the Institute. His manager, Mr. Henri Vaalin, who took a prominent part in organizing the previous meeting in Paris, has consented to act as honorary local secretary, and an influential reception committee is being formed.

Arrangements will be made for visiting the different sections of Metallurgy, Mining, Machinery, and Railway Plant at the Exhibition, under expert guidance; and Mr. Henri de Weddel, Bessemer Gold Medalist, has kindly intimated his intention to invite a limited number of the members to visit the works of his firm at Joeuf and Hayange, after the meeting.

Western Pennsylvania Central Mining Institute.

The summer meeting of the Western Pennsylvania Central Mining Institute was called to order in the Court House, Pittsburgh, Thursday, June 28, at 10 A. M., by President T. B. De Armit, and with a very good number of members in attendance.

After a few introductory remarks the president introduced Mr. Fred. C. Keighley, of Uniontown, Pa., who read a most interesting and exhaustive paper entitled "Bituminous Coal Mining Operations of the Past, Present, and Prospective Future."

The afternoon of Thursday was devoted to a visit to the Homestead mills of the Carnegie Steel Co., where a large number of members of the Institute were courteously shown through this interesting plant. Thursday evening a most instructing and interesting lecture on "The Geology of Pittsburgh Coal Fields" was delivered in the lecture room of the Carnegie Library by Prof. Edwin Linton, of Washington and Jefferson College. Friday morning, June 29, was given to the reading of the following papers: "Accidents in Coal Mines," by Thomas K. Adams, Mine Inspector, Mercer, Pa.; "The Progress and Prospects of Machine Mining in the Pittsburgh District," by Daniel Boden, Carnegie, Pa.; "Hints to Young Men Preparing Themselves for Mine Managers," by H. H. Stoek, Editor MINES AND MINERALS, Scranton, Pa. The session Friday afternoon was devoted to a discussion of these papers, which was very spirited and interesting.

The committee on publication reported that the proceedings of the Institute would be published in the near future. The president appointed a committee consisting of Messrs. Henry Louttit, Thos. K. Adams, and James Britt to prepare a report upon some means of preventing the use of inferior illuminating oils about the mines.

The attendance at this meeting was very much larger than at the last meeting in December, and was very good indeed for a summer meeting held during so busy a season. The increased interest in the work of the Institute reflects great credit upon its present officers, and the prospects for a large and enthusiastic meeting in December next are most encouraging. The papers read will not be extracted here, as many of them are of so much interest that they will be printed in full in coming issues of MINES AND MINERALS.

American Institute of Mining Engineers.

The seventy-ninth meeting of the Institute will be held in Canada, beginning the latter part of August, under the auspices of the Canadian Mining Institute. The sessions will be held at Sydney, Cape Breton, and Halifax, Nova Scotia; but for the convenience of members and guests from other quarters, the city of Quebec has been selected as a gathering point.

Parties arriving and reporting themselves at the Hotel Frontenac, in Quebec, a day or two before the departure of the special train for Sydney, as stated below, will enjoy, through the courtesy of the Canadian Mining Institute, special facilities for inspecting the characteristic features of that quaint and fascinating town.

A special train, composed of Pullman sleepers, dining car, baggage car, etc., will leave Quebec on the evening of August 19 and proceed direct to Sydney, Cape Breton, Nova Scotia, arriving there Monday evening. The provisional program, subject to minor changes, is as follows:

Tuesday, August 21.—Visit to steel works, now under construction, of the Dominion Iron & Steel Co., at Sydney, and the coal-handling plant at the International and other piers of the Dominion Coal Co.

Wednesday, August 22.—Excursion over the Sydney & Louisburg Railway, visiting the Caledonia, Dominion No. 1, Hub, Reserve, International, and other collieries of the Dominion Coal Co., and, time permitting, visiting the historic port of Louisburg. An alternate trip will be made to the old Sydney mines of the General Mining Association, worked as far back as 1785.

Thursday, August 23.—Sail through the beautiful Bras d'Or Lakes to Port Mulgrave, where the special train will be rejoined.

Friday, August 24.—Excursion to steel works and collieries at New Glasgow, Stellarton, Westville and other important mining districts.

Saturday, August 25, to Tuesday, August 28, will be spent at Halifax, where the members will be entertained officially and many side trips of a pleasant and interesting character will be provided by the Mining Society of Nova Scotia to the gold mines, the citadel, forts, etc.

Wednesday, August 29.—Arrival at Quebec of special train, returning from Halifax.

Arrangements can be made for a limited party to visit Newfoundland. They will take the steamer "Bruce" Thursday evening, August 23, to Port-Aux-Basques, connecting there on the following morning with the Newfoundland Railway, the transportation being furnished by Mr. R. B. Reid, proprietor of the railway, and proceeding to the Wabana iron mines of the Dominion Iron Co.; thence to St. John's, Newfoundland, where several days will be spent, and the return trip will be made by steamer "Buena Vista" (kindly placed at the disposal of the Institute by the Dominion Coal Co.) direct to North Sydney.

Applications and all correspondence on the subject of the special excursion train should be addressed to Mr. Theodore Dwight, Assistant Treasurer of the Institute, 99 John Street, New York, N. Y.

Colorado vs. Switzerland.

Switzerland, "The playground of Europe," is visited annually by over 15,000 American tourists and invalids. Why?

While the Alps have isolated peaks such as Mont Blanc (15,781 feet), and the Matterhorn (14,836 feet), the mean elevation of the highest Alpine chain is from only 8,000 to 9,000 feet. Colorado possesses more than 120 peaks over 13,500 feet in altitude, of which no fewer than 35 peaks range from 14,000 feet upward. In the whole of Europe, there are not over 12 mountain peaks of note.

The highest village in Europe is Avers Platz in Switzerland (7,500 feet); the highest inhabited point in Europe is the Hospice of St. Bernard in Switzerland (8,200 feet). In Colorado the mining town of Leadville, with 15,000 inhabitants, is 10,200 feet above sea level; other mining camps are still higher, and some gold and silver mines are worked at an altitude of over 12,000 feet.

The highest wagon road in Europe is said to be the Stelvio Road in Switzerland (9,170 feet). In Colorado the railroads cross the crest of the continent at Fremont Pass (11,328 feet), Marshall Pass (10,852 feet), and Tennessee Pass (10,433 feet). Switzerland does not possess, even in the famous St. Gothard line, any railroad engineering surpassing, if equaling, these. There are wagon roads over numerous passes in Colorado ranging from 12,000 feet upwards, the highest being Mosquito Pass (13,700 feet).

In Switzerland the cog-railroad from Vitznau to the summit of the Rigi Kulm (5,900 feet) has a length of $4\frac{1}{2}$ miles, in which the ascent is 4,072 feet. In Colorado the cog-railroad from Manitou to the summit of Pikes Peak (14,147 feet) has a length of $8\frac{1}{2}$ miles, in which the ascent is 8,100 feet, or an average of 846 feet per mile, the maximum grade being 1,320 feet.

One class of Switzerland's finest scenery is along the Via Mala, the Schyn Pass, and Urnerloch. In Colorado, the Cañon of the Arkansas with the Royal Gorge, the Black Cañon of the Gunnison, the Cañon of the Rio de las Animas, the Cañon of the Grand River, and others, are all much longer, quite as grand as and more varied in character than the best passes in Switzerland. The walls of the Cañons of the Grand River, the Gunnison, and the Arkansas rise to a sheer height of more than 2,000 feet.

It is unnecessary to speak of the mines and mills of the West located in the midst of scenery as grand as any to be found in the world.

As Colorado can be reached by at least one railroad—the Burlington—in one night from either Chicago or St. Louis, it is hard to understand why more Americans do not travel West instead of East in search of health and pleasure.

Interest Conveyed, Option.—Where a party by written contract bound himself to convey his gold interest with full warranty title, free from all incumbrances, the obligation to be of force for 12 months, if so long be necessary, only an option for 12 months was given, and if, at the expiration of that time, either party could not carry out the terms of the agreement, he was released therefrom.—*Love v. Love et al.*, 35 S. E. Rep. (S. C.) 398.

MINES AND MINERALS, VOLUME XXI.

THE results of the past year have caused us to plan for the coming year along lines very similar to those which years of experience have gradually shaped into the well known policies of MINES AND MINERALS.

We cannot hope to please everybody. There are some good people whom nothing earthly can satisfy, and these we must refer to publications that have superhuman sources of information.

That MINES AND MINERALS is reaching various classes of workers is well shown by four letters recently received within the space of a single week. One says, "MINES AND MINERALS contains all coal mining. Give us some metal mining." Another says, "I wish you would occasionally print a coal-mining article. You favor metal mining too much." Still another, "Can't you make MINES AND MINERALS more scientific? It is entirely too elementary"; and still another, "Your articles are entirely too technical and hard to understand. Make them simple."

These criticisms, by their diversity, lead us to think that we are accomplishing what we set out to do; that is, to furnish mining information which will interest any mining man, whether his mine be gold, silver, coal, clay, or what not. We do not aim to publish a gold paper, a silver paper, a copper paper, or a coal paper, but we do aim to publish just what our name signifies, that is, information about mines and minerals. This, of course, includes all allied and similar branches of engineering and industry wherever these allied branches touch upon the mining field.

The all-around man wants to know what is being done by others in lines similar to his own. If he is an up-to-date business man he has inside sources of information upon his immediate business, and does not wait to find out about it from a trade paper; but he does look to his trade and technical papers to tell him what people in similar lines of business are doing, so that he may profit by their experience and adapt their ideas to his own conditions.

Under similar conditions, the results to be obtained by mining are essentially the same whatever the material mined, so that no mining man can afford to be without information upon the technical progress of the whole mining world, if he wants to be up to date and if he wishes to conduct his own particular branch of the business with the greatest economy. The great trouble with mining men has been conservatism and adherence to precedents. The coal miner too frequently thinks that the metal miner can teach him nothing, and vice versa.

Volume XXI of MINES AND MINERALS will contain descriptions of new mining districts as they are discovered and opened up, and arrangements have already been made for detailed accounts of many of the new fields which are now attracting general attention and which have not already been described in these pages.

Most interesting descriptions of a number of recently installed mining and metallurgical plants are already in hand from districts extending from British Columbia, Alaska, and Ontario, on the north, to Alabama, Mexico, and Peru, on the south. A series of articles has been arranged for contrasting the mining practice of the old world, as it is exhibited at the Paris Exposition, with our own present practice. These articles will be prepared by the superintendent of one of the most progressive and up-to-date mining-machinery companies in the United States.

Through the cooperation of our subscribers the interest in the Correspondence Department of MINES AND MINERALS has greatly increased during the past year. The success of this department depends entirely upon the use made of it by subscribers. Its effectiveness has recently been increased, we believe, by answering directly from this office many of the questions received. Certain questions are left open for general controversy, as heretofore.

The descriptions of new machinery which appear from month to month are not, as many seem to suppose, advertisements for

which pay is received. Descriptions of new devices and appliances which are of interest to all mining men are always welcome, and whenever possible they receive a prompt and prominent place in our columns, and it should be understood that all such notices receive the same careful editing as any other reading article. Every effort is made to verify the claims of the builders or makers of such machinery or device.

The department of Examination Questions for Mine Managers, Mine Foremen, Fire Bosses, etc., is, we believe, being constantly improved, and every effort is being made to make these columns as helpful as possible to all those who are preparing themselves for such examinations. These State Examinations are becoming more and more rigid every year, while additional States are constantly adding such requirements.

Suggestions in regard to the conduct of any of these departments are at all times most welcome. If you have criticisms to make, send them to the editor, so that he may profit by them. Do not growl behind his back and then wonder why he does not do so and so, as you think it should be done. We are always glad to adopt practical suggestions if possible, or, if they cannot be adopted, to give a reason for not doing so. Write to us occasionally, suggesting subjects that would interest the people in your neighborhood, and we can usually arrange to furnish the desired information.

Finally, don't fail to carefully consult the advertising pages of MINES AND MINERALS whenever you wish to go into the market for mining machinery and appliances. A constant perusal of the advertising pages of any up-to-date journal is one of the best ways to keep in touch with the latest developments, and when writing to any advertiser mention where you saw his advertisement. It encourages him to advertise more freely, is a benefit to us, and gives you a better paper; for it is universally recognized that the amount and character of matter in the reading pages is a direct reflection of the amount and character of the advertising pages.

STRENGTH OF COAL.

AN editorial in the May issue of MINES AND MINERALS described some preliminary tests made by Mr. Wm. Griffith to determine the compressive strength of anthracite coal. The committee appointed by the Scranton Engineers' Club, to further investigate the subject, has perfected its plans for carrying out the tests as soon as the proper samples are secured. The following circular has been sent out asking for the cooperation of the coal operators of the Wyoming and Lackawanna valleys.

The committee of tests will be very glad to receive any suggestions in regard to the work, and would particularly like to receive the results of any similar tests that have been made.

SCRANTON ENGINEERS' CLUB.

SCRANTON, PA., July 18, 1900.

DEAR SIR:—At a recent meeting of the Scranton Engineers' Club, Mr. William Griffith, of Scranton, reported the result of a few tests which he had made to determine the compressive strength of anthracite coal.

These preliminary experiments indicate that different seams in the same colliery have very different compressive strengths, and if this be the case, the present practice of laying out the pillars without respect to the compressive strength of the coal might be changed with great advantage to the operator in saving disastrous and expensive results. Such information would also afford a means of determining where larger pillars were necessary, where smaller ones could be used with safety, and whether any part of a mine is likely to cave or squeeze, etc.

These preliminary tests and Mr. Griffith's suggestions so impressed the Scranton Engineers' Club, that a committee has been appointed to investigate this subject. The Dickson Mfg. Co. has courteously extended to this committee the privilege of using its testing machines, and the authorities in charge of the testing laboratories at Cornell University and the Pennsylvania State College have offered to test, free of charge, any specimens that may be sent to them.

The value of the results obtained by these tests will depend very largely upon the number of samples which it is possible to procure, and the extent of the territory from which these samples are obtained.

Will not your company assist in this work by having a number of specimens prepared in accordance with the following specifications and sending one set prepared and properly labeled to each of the following addresses: One set to Mr. William Griffith, Coal Exchange, Scranton, Pa.; one set to Prof. R. C. Carpenter, Professor of Experimental Engineering, Cornell University, Ithaca, N. Y.; one set to Prof. Louis E. Reber, Pennsylvania State College, State College, Pa.

These specimens should be prepared as follows: (1) One specimen should be exactly cubed, and should be 2 inches on the side. (2) A piece of the same coal, 2 in. × 2 in. square and 4 inches high. (3) A piece of the same coal, 2 in. × 2 in. square and 1 inch high. If only one sample can be furnished the cube is preferred. The base of the sample should be parallel to the bedding plane of the coal.

Each set of the specimens should be of the same quality, and, if possible, sawed out of one large lump.

Each specimen should be carefully labeled and described on one of the enclosed blanks and wrapped with the label inside of the wrapper. If you can send only one set kindly forward that to Mr. Griffith, prepaid.

A report of these tests will be furnished to all who assist in any way in carrying out the tests.

Kindly fill out the enclosed postal card signifying whether you will assist us in this work and return the same at once stating what specimens you can furnish, from what locality and coal seams these specimens will be taken, and how many sets of samples you can send.

Committee { Wm. Griffith, Chairman,
J. H. FISHER,
MORGAN DAVIS,
HARRY E. YEWENS,
H. H. STOEK.

A copy of this circular letter has been sent to the superintendent of every mine in the Lackawanna and Wyoming valleys as given in the last report of the Bureau of Mines.

DESCRIPTION OF THE SPECIMEN.

1. Location of colliery; 2. Operator; 3. Size of specimen; 4. Seam from which taken; 5. Location from which taken, i. e. near basin, outcrop, or saddle; 6. Pitch of the seam; 7. Character of the coal—glassy, checker, bright, or dull; 8. Depth below surface; 9. Face coal or pillar coal; 10. If pillar coal, how long has pillar been standing?

UNITED STATES GEOLOGICAL SURVEY.

THE last session of Congress recognized, in a fitting and substantial way, the increasing importance and value of the work of the United States Geological Survey.

This survey is at present the chief representative of the mining interests in the Federal Government, hence any contemplated action upon the part of Congress which will increase its efficiency should receive the hearty support of the mining fraternity.

For many years there were two prime causes of complaint against the Survey in mining circles:

1. The great delay in printing the reports of work done.
2. The small amount of economic work which was carried on, and the very small amount of attention given to practical mining.

The former defect has been largely remedied, during late years, by the prompt appearances of preliminary reports, which are now published as soon as the information is collected, without waiting for the complete volume of statistics, official reports, etc.

The answer to the second question has always been that the appropriations made by Congress did not permit of any enlargement of the work of the Survey, which was, of course, primarily for scientific and geological work. The increased appropriations of the last Congress are a step towards the removal of this reason, and mining men throughout the country will await with interest some results that will appeal to them more directly than do the purely scientific reports. This is not intended in any way as a reflection upon the character of these reports, whose value is too well known, but is simply a statement of facts as they appear to the miner.

A letter recently received from Mr. Walcott, Director of the United States Geological Survey, shows that with the increased appropriation more extended economic work is to be undertaken, while the enlargement of the chemical and physical laboratories should permit of work being carried on of direct and important interest to the practical side of mining. Mr. Walcott says:

"Congress increased the appropriation for Geology \$60,000, and Mineral Resources \$20,000. With this increase we have been able to reorganize the geologic work so as to provide for a considerable extension of the economic work of the Survey.

"The division of Mineral Resources will continue the collection of mineral statistics, including those of gold and silver as mineral products, and in addition, this division will be charged with the important function of keeping the Survey in touch with mining schools and bureaus, and economic work of the various State Geological Surveys.

"The division of Chemical and Physical Researches is to be enlarged by the installation of needed chemical and physical apparatus, and the doubling of

the force employed, and of the space allotted to the laboratories. This division will cooperate with the division of Mineral Resources and the section of Economic Geology.

"The section of Economic Geology is organized with Mr. S. F. Emmons in charge of the investigations of metallic ores, with the exception of iron, which is in charge of Prof. C. R. Van Hise. Dr. C. Willard Hayes will have charge of the investigations pertaining to the non-metallic economic products. The section of Economic Geology will cooperate with the sections of Areal, Pleistocene, and Pre-Cambrian and Metamorphic Geology, and division of Mineral Resources.

"The sections of Areal and Pleistocene Geology will have charge of the areal mapping and stratigraphic work connected with the distribution of all sedimentary rocks. This includes the mapping of all mineral deposits which have occurred in any considerable areal distribution.

"The division of Hydrography was greatly strengthened by an increase of \$50,000 in its appropriation. Under this, economic questions pertaining to the distribution and utilization of the water resources of the country, including irrigation and power, will be carried forward to a greater extent than has been possible heretofore.

"As a whole the Survey stands in a better position to aid the mineral producers of the country than ever before. If as much progress is made at the next session of Congress, matters will be in a very satisfactory condition."

The work of the Survey in the past speaks for itself, and it is hoped that Congress will continue the liberal policy begun at the last session, so that the plans now being inaugurated may be successfully carried out.

Book Review.

JOURNAL OF THE MINING SOCIETY OF NOVA SCOTIA, Volume V.

BULLETIN OF DEPARTMENT OF LABOR, No. 28, Washington, D. C.

MINE DEVELOPMENT THE BASIS OF PROSPERITY, by Almarin B. Paul, M. E., San Francisco, Cal.

GEOLOGICAL SURVEY OF MISSOURI. Volume XII, Part I. Report on Green County, by Edward M. Shepard.

GOLD MEASURES OF NOVA SCOTIA AND DEEP MINING, by E. R. Faribault, B. Sc. Published by the Mining Society of Nova Scotia, Halifax, N. S.

OBJECTS AND POSSIBILITIES OF CREDIT MEN'S ASSOCIATIONS. An address given before the Rochester Credit Men's Association, at Rochester, N. Y., April 17, 1900, by Daniel B. Murphy.

PROPOSED STANDARD SPECIFICATIONS for steel bridges, ships, buildings, boiler plate, rivets, steel rails, spliced bars, axles, tires, forgings, castings, and specifications for wrought iron; also the report of the American Branch of the Committee of the International Association for Testing Materials. J. M. Porter, Secretary of Publication Committee, Easton, Pa.

GEOLOGICAL SURVEY OF ALABAMA. Report of the Warrior Coal Basin, by Henry McCalley, Assistant State Geologist, University, Ala. 327 pages, illustrated. This report contains an introductory chapter of 8 pages, which gives a general description of the Warrior Coal Field, and is followed by separate chapters upon the Black Creek, Horse Creek, Pratt, Gwin, and Brookwood groups of coals. An appendix contains records of drillings and shafts.

SUPPORT YOURSELF WHILE LEARNING A PROFESSION. An interesting story of young men who have fitted themselves for good positions in architectural, mechanical, and electrical engineering work is told in this little book. Its motto is "to earn more, learn more" and the value of a technical education and the ease with which it may be acquired are illustrated with many examples of young men who have spent their spare time in study and risen from the ranks to important positions in professional life. The book will be sent free on application to The International Correspondence Schools, Scranton, Pa.

ENCYCLOPEDIA OF MEXICAN MINING LAWS, by Richard E. Chism, Ph. D., City of Mexico, Mexico. Price \$2. 201 pages. This handy volume should be of great value to all who are interested in Mexican mining matters, as it contains, alphabetically arranged, a large amount of information in regard to Mexican laws. This information is rendered easily available by a comprehensive index of 32 pages, which adds greatly to the value of the book. It also contains as an appendix, a glossary of Mexican mining terms. Mr. Chism has certainly presented, in a very neat form, information that will be particularly acceptable at the present time when there is so much interest being taken in mining matters in the Spanish-American countries.

MECHANICAL EQUIPMENT OF THE NEW SOUTH STATION, BOSTON, MASS., by Walter C. Kerr. A paper read before the American Society of Mechanical Engineers, December 18, 1899. This paper describes the equipment of the station in detail under the following heads: Powerhouse; Interlocking Switch and Signal System; The Electric Plant; Heating and Ventilating; Disposal of

Drainage from Waterproofed Structure; Roof Drainage; Ice-Making, Refrigerating, and Water-Cooling Plants; Car Heating in Train Shed and Yards; Air-Brake Charging; Steam and Hot-Water Supply to Head House; Fire Protection; Elevators, Baggage and Express Lifts. It will be of unusual interest to any one identified with these branches of engineering, as the descriptions given here are detailed and the illustrations very profuse. Copies of this paper can be secured from the Publishing Department of the Westinghouse Co., Pittsburgh, Pa.

THE CYANIDE PROCESS, by J. Parke. A practical book published by C. Griffin & Co., Limited, London, and J. B. Lippincott & Co., Philadelphia, Pa. Bound in cloth. Price, \$2. This is the first English edition of the valuable work on the cyanide process, which has gone through three editions in New Zealand. The text is fully illustrated by cuts, many of which are in the form of large folders. Some very valuable information has been added upon the cyanide treatment of slimes and antitoxes for potassium cyanide poisoning, also an appendix treating of the special method of cyaniding now in use in New Zealand, in which the ores are practically all crushed wet. This book has already made its name as an extremely handy manual for any one interested in this process, and in its present revised form it should be welcomed not only by those already familiar with it, but by all who are interested in the recovery of the precious metals by this process.

HORSELESS VEHICLES, AUTOMOBILES, MOTOR CYCLES, OPERATED BY STEAM, HYDROCARBON, ELECTRIC, AND PNEUMATIC MOTORS, by Gardner D. Hiscock. M. E. Norman W. Henley & Co., 132 Nassau Street, New York. Price, \$3. Those who have read the earlier works of the author of this book will not be disappointed with this, his latest effort. It is made up very largely of catalogue descriptions and illustrations of nearly every type of motor vehicle that has been introduced in America up to the present time. The general reader who is interested in knowing what has been done in this field and who cares more for an outline of the leading features of the different types than for accurate technical information will find much that is interesting and some that is instructive in the pages of this book. The engineer, however, who has given the development of horseless locomotion some study will find nothing in it that will be new, while the student who wants principles or the designer who is searching for practical information that will assist in the proportioning of vehicles or the motors and gearing by which they are propelled will find that these points are as carefully concealed as they are in the catalogues of the most conservative builders.

THE INDIANA DEPARTMENT OF GEOLOGY AND NATURAL RESOURCES, TWENTY-FOURTH ANNUAL REPORT, 1899, W. S. Blatchley, Indianapolis, Ind. 1,078 pages, illustrated. This report contains a chapter upon the natural resources of Indiana by the State Geologist; the reports of the State Inspector of Mines, of the State Natural Gas Supervisor, and of the State Supervisor of Oil Inspection. Also the following reports upon natural history subjects: General Discussion of the Middle Silurian Rocks of the Cincinnati Anticlinal Region, with their Synonyms, by August F. Foerste; Report upon the Waldron Shale and Its Horizon, by J. A. Price; Dragonflies of Indiana, by E. B. Williamson; Batrachians and Reptiles of Vigo County, by W. S. Blatchley; Catalogue of the Flowering Plants and of the Ferns and Their Allies Indigenous to Indiana, by Stanley Coulter. The report of the State Inspector of Mines shows the coal trade in the State to have been of a very satisfactory condition during the year 1899, with good prices, a firm market, and a demand in excess of the supply, and with comparatively few labor troubles. Nine new mines were opened up during the year and a new coal field is reported as having been entered by the Indiana Southern Railroad. This report also contains the Terre Haute agreement between proprietors and miners extending from April 1, 1899, to April 1, 1900; also the usual statistical tables of production, accidents, etc. The Inspector, Mr. Epperson, emphasizes the necessity for more complete and accurate mining maps. He also makes suggestions as to need of legislation in Indiana, and closes his report with a description of a number of the mines in the State and with an account of the Indiana Mining Institute for the year.

METALLURGY OF SILVER. By H. F. Collins, being Part II of the Metallurgy of Lead and Silver of Griffin's Metallurgical Series. Edited by Prof. Roberts-Austen. Published by Charles Griffin & Co., Limited, London, and J. B. Lippincott & Co., Philadelphia, Pa. Bound in cloth. Price, \$4.50. The general style and arrangement of this work are similar to those of the metallurgy of lead. Tables of comparison form a very important feature of the work, as do the comparison of advantages and disadvantages of the various processes, which are arranged in columns on the same page so that the advantages and disadvantages come parallel with one another. The author states in the preface that obsolete processes have been only casually mentioned,

the idea being that any one who is interested in historical metallurgy would do better to consult pages of authors who were more nearly contemporary with the processes they describe, the aim of the work being to furnish a practical book for working metallurgists. The work covers a discussion of silver and its ores, amalgamation processes, including the patio, Cazo, Fondon, Krohnke, and Tina processes, the pan process, the roasting and amalgamation processes with pans or barrels; the treatment of tailings and the concentration of silver ores, and the retorting, melting, and assaying of silver bullion, and the chloridizing-roasting; the lixiviation processes are then taken up, including the Augustin, Claudet, and Ziervogel processes, the hyposulphite and leaching processes and practice, and the refining of lixiviation sulphides. The next section treats of smelting processes, including matte smelting in the blast furnace, pyritic smelting, matte smelting in reverberatories, the treatment of argentiferous mattes, and silver-copper smelting.

THE METALLURGY OF LEAD, by H. F. Collins, being Part I of the Metallurgy of Lead and Silver which belong to the Griffin metallurgical series. Edited by Prof. Roberts-Austen. Published by C. Griffin & Co., Limited, London, Eng., and by J. B. Lippincott & Co., Philadelphia, Pa. Bound in cloth. Price \$1.50. This book fills a gap in the series of metallurgical literature by describing the processes used in Australia, and treating the English work from an English standpoint. For the American work on this subject the author acknowledges his indebtedness, in a large degree, to Hoffman's Metallurgy of Lead, and for the German practice, to Schnabel's work on the same subject. The work is very clearly arranged, and contains many illustrations. One interesting feature of the work is the careful, systematic arrangement of information in tables. These tables cover most of the features of the subject, comparing the ore treatment, products obtained, including slags, mattes, etc., comparison of methods used in different districts, costs, and many other interesting factors. These tables bring the matter before one in a manner totally impossible to accomplish in the ordinary text style. The scope covered by the work includes the sampling and assaying of lead and silver ores, which has been reduced to as narrow limits as possible, the assumption being, evidently, that this matter belongs more to the assayer than to the metallurgist, and the space in the book being reserved largely for the metallurgical treatment. The properties of lead, its principal compounds, and lead ores, are thoroughly treated, after which lead smelting is taken up in its various branches, including smelting in the reverberatories, in hearths, the roasting of lead ores, blast-furnace lead smelting, including both the principles and the plant required, blast-furnace products, samples of blast-furnace work, flue dust, its composition, collection, and treatment, cost, losses, and the purchase of ores; treatment of zinc-lead sulphides, desilverization, including the shipping and refining for market, the Pattinson process, the Parke's process, and the cupeling and refining of the products.

GAS-ENGINE CONSTRUCTION. A Practical Treatise Describing the Theory and Principles of the Action of Gas Engines of various Types, and the Design and Construction of a Half-Horsepower Gas Engine, by Henry V. A. Parsell, Jr., and Arthur J. Weed, M. E. Norman W. Henley & Co., 132 Nassau Street, New York. Price, \$2.50. This is preeminently a book for the amateur and contains only so much of theory as is required to enable the beginner to understand the general principles on which the action of the gas engine depends and the purpose of the various parts that enter into the construction of the more common types of this motor. The descriptive matter is also limited to the illustration of a representative engine of each of the different classes, with a brief explanation of its leading features. The greater part of the space is taken up with directions for the construction of a 2½ in. × 4 in. horizontal four-cycle gas or gasoline engine, rated at ½ horsepower. Complete working drawings of all the details, together with very thorough instructions for performing the different operations involved in their construction are given. The instructions cover all the different steps of patternmaking and machinery, and are made particularly clear by means of halftone reproductions of photographs of the patterns, the methods of fastening the work in the lathe for the different operations, and of the various steps involved in finishing the parts and assembling them. The work is so designed that the only machine actually required in finishing all parts of the engine except the flywheels is a lathe with an 8-inch swing. With this and the requisite small tools any careful amateur can, by following the instructions given, feel confident that his labors will be rewarded by the production of a successful motor.

CATALOGUES RECEIVED.

In writing for catalogues, please mention Mines and Minerals.

RUE MFG. CO., Philadelphia, Pa. "Injectors." 8-page pamphlet.

GENERAL COMPRESSED-AIR HOUSE-CLEANING CO., St. Louis, Mo. "Compressed-Air House-Cleaning."

DETROIT LUBRICATOR CO., Detroit, Mich. 56 pages, showing many different types of lubricators manufactured by them.

FAIRBANKS, MORSE & CO., Chicago, Ill. "Hoists and Air Compressors." Handsomely illustrated and well gotten up.

HIBBARD-RODMAN-ELY SAFE CO., New York City, N. Y. 4-page circular, describing "The New Manganese Steel Bank Safe."

CHAS. L. HEISLER, Erie, Pa. Circulars describing the Heisler Steam Road Roller and the Heisler High-Duty Pumping Engine.

H. K. PORTER CO., Pittsburg, Pa. "Light Locomotives," 236 pages, very nicely illustrated, and giving price lists, etc., of these locomotives.

DEAN BROS. STEAM PUMP WORKS, Indianapolis, Ind. "Duplex Steam Pumps." Catalogue No. 38. 40 pages, nicely gotten up and well illustrated.

MEITZ & WEISS, New York, N. Y. "Gas and Kerosene Engine." 24 pages, showing different views of this engine and a number of places where they are in use.

NORTH AMERICAN METALINE CO., New York City, N. Y. 24-page circular, containing testimonials from many of the large mining companies, etc., who have used metaline.

BALDWIN LOCOMOTIVE WORKS, Philadelphia, Pa. "Record of Recent Construction" No. 19, May, 1900. 32 pages, with views of the many different styles of locomotives built by this company.

JACKSON DRILL & MFG. CO., Denver, Col. "The Jackson Hand-Power Rock Drill." 16 pages, showing the use of these drills in mines and giving a number of testimonials from mining companies using them.

HOOVER PNEUMATIC MILLING CO., P. O. Box 200, Baltimore, Md. Small pamphlet describing a modern dry method of milling ores, the Kent mining mill pulverizer, and the Sturtevant centrifugal rolls for dry pulverizing.

JEFFREY MFG. CO., Columbus, Ohio. "Jeffrey Coal-Mining Machinery." 76 pages, handsomely illustrated, showing a great many different types of machines and also a number of places where these machines are in use.

FRASER & CHALMERS, Chicago, Ill. "Hoisting Engines and Appliances." 120 pages, describing their single-drum hoisting engines, double-drum hoisting engines, conical-drum hoisting engines, reel hoisting engines, and horsepower hoist.

WEBER GAS AND GASOLINE ENGINE CO., Kansas City, Mo. "Gas and Gasoline Engines and Hoists." 72 pages, describing the economy, efficiency, material, workmanship, design, and strength of the engines and hoists made by this well known firm.

BULLOCK ELECTRIC MFG. CO., Cincinnati, Ohio. Souvenir of the Master Mechanics' and Master Car Builders' Convention, Saratoga, N. Y., June 18 to 23, 1900. Handsomely illustrated, containing views of the different departments of the offices of this firm, and also a number of the machines manufactured by them.

GENERAL ELECTRIC CO., Schenectady, N. Y. Price List No. 7,523, "Sockets and Receptacles"; Bulletin No. 4,223, "The Thomson Recording Wattmeter for Street-Railway Service"; No. 4,224, "Air Blast Transformers"; No. 4,225, "Direct-Driven Continuous-Current Generators for Lighting and Power." Flyer No. 2,055, "Pendant Push-Button Switches."

In their semimonthly review of the lead and zinc mining district, dated June 30, 1900, the Lyon & Leddy Co., Joplin, Mo., says: The close of the first six months of the present year finds zinc ore selling at from \$25 to \$26 per ton, as against \$44 per ton one year ago, while lead is now quoted at \$24 per thousand pounds on a strong market, as against \$26 for the corresponding period last year. During the past week lead advanced \$5 per ton over the preceding week, while zinc is lower by from \$1 to \$2 per ton.

The total production for the six months ending June 30 amounted to 129,462 tons of zinc and 14,105 tons of lead, at a value of \$4,367,082. This is 3,964 tons less zinc, 2,177 tons more lead, and \$1,412,095 less in value than the production of the first six months of 1899. Compared with the same period of 1898 it is an increase of 20,173 tons of zinc, a decrease of 459 tons of lead, and an increase of \$1,235,277 in value.

CORRESPONDENCE.

This Department is intended for the use of those who wish to express their views, or ask or answer questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided. All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith. The editor is not responsible for views expressed by correspondents in this Department. Correspondence should be in as simple language, and as free from technical terms and formulas as possible, consistent with clear solution. Questions on subjects not directly connected with mining will not be published.

Effect of Gasoline Engine on Ventilation.

Editor Mines and Minerals:

SIR:—What would be the effect of a gasoline engine upon the ventilation of a mine? Yours truly,
Birmingham, Ala. JAS. DAVIS.

Messrs. Fairbanks, Morse & Co., of Chicago, have replied to the above inquiry as follows: Without knowing the exact location and conditions, it is rather difficult for us to advise you fully upon the subject of using a gasoline engine in a mine, but would say that we have one or two engines direct connected to pumps which are installed in mines for the purpose of pumping water. The engines in question are back in tunnels such a distance that an exhaust pipe would have been very expensive, and the engine has been installed so that the exhaust was carried to the top of the tunnel and allowed to escape. The heated air, which is about all that there is of the exhaust from our engines, works its way along the top of the tunnel to the vertical shaft. The engine drawing in fresh air from the floor of the tunnel and exhausting hot air at the top, would have a tendency to set up an artificial circulation of air in the mine. If there was no ventilation in the tunnel, we rather think it would be best to use an exhaust, even though it were a considerable length, as this would do away with any possible fouling of the tunnel. Sometimes it can be arranged to bore a small hole down to the tunnel, and this hole, by extending the pipe a few feet into the same, can then be used as the exhaust conduit, and the draft caused by the exhaust will also assist in ventilating. So far we have never found a case where we could not arrange to install gasoline engines for pumping.

Horsepower of a Boiler.

Editor Mines and Minerals:

SIR:—Which is the correct method of ascertaining the horsepower of steam boilers? Here is an example: One cylinder boiler 36 feet long, 36 inches in diameter; 80 pounds steam pressure. What is the horsepower of the above boiler? Yours truly,
Taylor, Pa. W. B. OWEN.

The horsepower of a boiler is calculated most accurately when we know the weight of water evaporated per hour and the temperature of the feedwater, by dividing the weight of water evaporated (lb. per hr.) by 34.5, and multiplying the quotient by a factor taken from a table giving the factor of evaporation. Such tables are published in many steam engineer's handbooks. For example, if the boiler requires 45 gallons of water per hour, and the temperature of this feedwater is 40° F., since the factor of evaporation for 80 pounds gauge pressure and feedwater at a temperature of 40° F. is 1.214, we have in this case, using the above formula,

$$H = \frac{45 \times 8\frac{1}{2} \times 1.214}{34.5} = 13.195 \text{ H. P.}$$

It is usual practice, however, for boilermakers to calculate the horsepower of a boiler from its heating surface, for different types of boilers; dividing the heating surface by a factor, which experience has shown to be approximately correct for a given type of boiler. The factors in common use for this purpose are given in the following tables:

Type of Boiler.	Heating Surface per H. P. (sq. ft.).
Cylinder	6 to 10
Flue	8 to 12
Tubular	14 to 18
Vertical	15 to 20
Water tube	10 to 12
Locomotive	1 to 2

In the present case, assuming that $\frac{1}{2}$ of the perimeter is heated throughout the entire length of the boiler, we have,
 $3.1416 \times 36 \times 36 = 113$ square feet heating surface. For this
 3×12
 type of boiler, according to the style and size of the firebox, there is considerable variation in the number of square feet of heating

surface per horsepower (6 to 10 sq. ft.). Assuming 9 square feet of heating surface per horsepower, we have $\frac{113}{9} = 12.55$ H. P.

The Relation of Magnetic Iron to Copper Ores.

Editor Mines and Minerals:

SIR:—As magnetic iron frequently forms the capping of copper lodes, is it a generally accepted theory that magnetic iron has its origin in the decomposition or oxidation of such copper minerals as chalcopyrite? Yours truly,

Port Renfrew, Vancouver Island, B. C. LEWIS KIRKPATRICK.

We think not.

Size of Shaft.

Editor Mines and Minerals:

SIR:—I am not in the habit of bothering any person, but I would be very thankful if you would please give me the size of a shaft, inside of timbers, to suit the following conditions: Shaft to have three compartments, two hoistingways, one airway; capacity of mine cars, 2 tons; depth of shaft, 250 feet; coal seam nearly flat, 8 feet thick, and generating much gas, and to hoist 1,000 tons per 10 hours. The mine will have 400 men and 20 mules.

Yours truly,
J. H. S.

Haffey P. O., Pa.

One thousand tons in 10 hours = 100 tons per hour; and since the capacity of the mine car is 2 tons, $\frac{100}{2} = 50$, is the required number of trips per hour. With a good equipment at the upper and lower landing of this shaft, we can reduce the time of hoisting, or increase the number of trips per hour to a considerable extent, which would reduce the size of the mine car required. We offer this simply as a suggestion, since a mine car of 2 tons capacity is not always easily handled at the face. The height of the seam being 8 feet, we would adopt a mine car having the dimensions marked in the accompanying sketch, and having 14-inch or 16-inch wheels. With these dimensions, the car may be made 6 feet long, inside measurement, and may be loaded 10 inches over the top of the car, which would require a height above the top of the ties of 5 feet 4 inches in the clear, or say 6 feet. This can readily be obtained in an 8-foot seam. The inside length of the car being 6 feet, the width of the shaft should not be less than 8 feet in the clear. As shown in the sketch, the clearance between the guides should not be less than 4 feet 10 inches, and using 4-inch guides, the size of each hoistway will be (5 ft. 6 in.) $\times$ 8 ft. The size of the pumpway should not be less than 5 ft. $\times$ 8 ft. in order to give ample room for a ladderway, if desired, and for the necessary pipe lines. Using 6-inch bunting between these several compartments, we have for the size of the shaft in the clear 8 ft. $\times$ 17 ft. It is always good practice to have the hoisting shaft of a size sufficient to meet every emergency that may arise, although on account of the expense of excavation and the timbering, the size of the shaft should not be larger than what is required.

Haulage Problem.

Editor Mines and Minerals:

SIR:—If the modulus of elasticity is 29,000,000; the elastic limit 57,000 pounds; the working load is one-fifth of the ultimate strength of the rope, which is 1 inch in diameter composed of six strands of seven wires each, or a total of 42 wires, of material that has a breaking strain of 201,600 pounds per square inch, (1) what is the minimum diameter of drum on which this rope may be used? (2) What is the bending strain? (3) What is the radius of a curve, on which 8-inch sheaves are set 3 feet apart, that will give the same bend in the rope at each 8-inch sheave, as if the rope were going round a sheave of minimum diameter for this rope? (4) What in case (3) will be the bending stress? The writer is familiar with lots of literature on these points, but there is such a wide variation in the results that he consulted lots of his friends on the subject to find that they are as much at sea as himself, or if the results are satisfactory to them they will agree with nothing else.

The writer is familiar with makers' statements as to size of drums in their catalogues; but how do they arrive at the sizes? Will some able correspondent thrash these points out for the benefit of your many readers?

Lethbridge, Alta., Can.

Yours truly,
H. L. D. W.

Value of Coal Lands.

Editor Mines and Minerals:

SIR:—I have very pressing need of some reliable estimate of the value of unimproved coal lands in Pennsylvania. Can you tell me what such lands are generally in your State considered to be worth? I mean lands holding at least one seam of bituminous coal 3 feet or more in thickness, and of quality that would make it always salable? I know that proximity to railroad lines would be an important item, so please say what such lands would bring when near railroad, for that would be about the kind that I am asking about. Also, are lands leased on royalty in your State, and if so, at about what rate per ton? Are sales based upon royalty estimates, i. e., upon the calculation of so many tons of coal to the acre? I hope I shall not be taxing your time too much in asking you to give me this information.

Yours truly,
S. A.

Bituminous coal lands such as you describe sell in Pennsylvania at the present time for from \$25 to \$50 per acre. Several tracts of this character, having good railway connections, have sold at \$27, \$35, and \$40 per acre, respectively. A large tract of bituminous coal land in the western part of Pennsylvania which was sold for \$7 per acre in 1892 is, we are told, now held at \$50 per acre. Similar lands are held in West Virginia at about the same figure or possibly slightly less. These figures apply to non-coking coals, and the values for coking coals are considerably higher. As you know there has been great activity in the coking coal lands of Western Pennsylvania during the last year, and a great many deals have been reported in which the price paid was given as \$1,000 per acre. These prices are probably accurate for coal lands bordering on the celebrated Connellsville coal region. Sales of coal lands in this State are not based on royalty estimates but are straight out-and-out sales. There are a great many royalty leases in this State, and the royalties on bituminous coal, non-coking, vary from 5 to 12½ cents per ton. Coking coal royalties are higher, and we know of one such royalty of 17½ cents per ton, and another of 15 cents per ton for the first five years with an increase of 1 cent per ton for every five years. Anthracite royalties are very much higher, varying from 25 to 50 cents per ton, depending largely upon the date at which the leases were made. The present average royalty would probably be about 40 cents per ton, though in exceptional cases, 55 and 75 cents have been obtained.

Coeur d'Alene District, Idaho.

Editor Mines and Minerals:

SIR:—The commencement, this week, of shipments from the Terrible-Edith, a mile above Murray, marks an era in Coeur d'Alene mining. Situated within six miles of the first discovery of gold in the Coeur d'Alenes, these claims lay untouched for almost 17 years, although they were located within a year after the first rush into Eagle, in 1883, and it was known at that time that there was an abundance of carbonate of lead and some galena on the surface where the discovery was made. Since their location the annual assessment work has been done in a tunnel which was being run on the end line common to the two claims, and this spring, when in 250 feet, the vein was cut, showing 4 feet of lead ore, nearly all of which would bear shipment, although it necessitated a haul by wagons of 17 miles over two ranges of mountains. The drifting since has been to the west, and the vein has widened to 7 feet between walls, although the ore is not so good as where first cut, and only a small part of it will bear shipment without concentration. Six or eight miles east from there, nearer the head of Prichard Creek, there is a lead-bearing belt on which are three or four claims which have shipped ore, it being hauled by wagons to Thompson Falls, Mont., the claims being so near the summit of the Bitter Root range that there was but little mountain to climb with the ore, but this from the Terrible-Edith is the first from near Murray.

The further development of the property will be closely watched by local students of mining methods and conditions, as it appears to be different from any of the developed claims in that district. It was at first considered a strictly gold-bearing region, the presence of lead ore being known to but few and overlooked by them. The ledges are usually of the blanket class, only dipping from 10° to 20° from the horizontal, and carry no mineral in quantities except gold and iron, there being enough silver with the gold to make the common value from \$15.50 to \$16.50 per ounce. Occasional traces of copper are found, but never more than traces, while lead and zinc were unknown. So far as the writer is informed, aside from the Terrible-Edith, no

lead-bearing vein there has been developed to any considerable extent, although a number of others are known to exist, including one of sand carbonate from which lead can be extracted in an ordinary blacksmith's forge. One mammoth vein on the Daddy carries some lead, together with gold, silver, and a little copper, but it has never been worked. A noticeable difference between the lead- and gold-bearing veins is that the former are nearly perpendicular, although there is at least one gold-bearing vein of the same nature. They are also larger than those in which gold forms the principal value, the latter usually being from 6 inches to 2 feet, and narrowing down to a knife blade as often as they widen to over 4 feet. Whether or not there are other differences cannot be told until there is more development work in the lead ores.

A number of other lead discoveries have been made in the neighborhood this spring, and the renewed hope of getting a railroad to Murray will stimulate work on them this year, as the development of any considerable bodies of lead ore would be a powerful stimulus to railroad men to build, and there is likely to be considerable light thrown on the secrets of the Coeur d'Alene "gold belt" before the century ends.

Yours truly,
Wallace, Idaho.
W. C. CLARK.

Centrifugal Ventilators.

Editor Mines and Minerals:

SIR:—The version which Mr. Beard puts on the mathematical proof of approximate identity which I have shown for pav and

$Q_0 p_0 \log \text{nat } \frac{p_1}{p_0}$ is not correct. The demonstration merely shows that Qp is an approximate value of the work of compression which makes it identical with the work done by the total pressure pa on the cross-section of the airway, exerted through the distance v , and no more.

It is true that the compressive formula may be written as $Q_1 p_1 \log \text{nat } \frac{p_1}{p_0}$ in place of $Q_0 p_0 \log \text{nat } \frac{p_1}{p_0}$, but it is the latter

form which, after substituting the approximate value of $\frac{p_1 - p_0}{p_0}$

for $\log \text{nat } \frac{p_1}{p_0}$, and when disregarding the compressibility of air within small variations of pressure, gives us the equation, $u_c = Qp$.

Referring to Mr. Beard's comment on my Nos. 3, 9, and 10, I must declare that I cannot see that matter in his light. To my mind it is and remains a radical difference.

I fully concur with Mr. Beard when he says that "in any circulation the pressure p varies with the square of the quantity." The quantity Q is proportional to the velocity v in the airway, hence p varies also with the square of v . The resistance (ks^2) of the airway also varies as the square of v . The force applied to the resistance must be proportional to the latter, and hence must also vary as the square of v , or it must be proportional to p . Since double the quantity creates a four-times-greater resistance, the force must also be four times greater. Our force is the centrifugal

force $\frac{W}{g} \times \frac{V_p^2}{\rho}$, which becomes four times greater by doubling V_p , or n . Hence, double the n means double the quantity, or the yield of a fan is proportional to its speed; the pressure varies as the square of the speed. This much for the present, as a denial of Mr. Beard's claim that " Q varies as $\sqrt[3]{n^4}$, and p varies as $\sqrt[3]{n^8}$."

In my No. 5 I have defined $U = m \times f \times \frac{f}{2} = \frac{1}{2} m f^2$ as the work of acceleration of the constant force $m \times f$ when acting upon mass m , during the first second only. Mr. Beard has paid no attention to this limitation of the formula. A brief retrospect will throw an interesting side light upon this phase of our controversy, and will positively dispose of it. In all his papers on this subject, up to date, Mr. Beard says: $U = m f \times \frac{f}{2}$ is the work of

acceleration of the constant force f for each second. Here is how he came to commit this error. At the conclusion of a discussion which he had with Prof. Sperr (Colliery Engineer, August, 1895), he recommends a study of Ganot's "Elements de Physique" (translated by E. Atkinson) and quotes from it: "When a constant force acts on a mass so as to change its velocity, the work done by the force is equal to half the product of the mass into the change of the square of the velocity." Continuing, he says: "The change of the square of the velocity, for a unit of time, would be the square of the acceleration" (evidently construing "the change of the square of the velocity" as equivalent with "the square of the change of the velocity"). The formula which is paraphrased by E. Atkinson in the above language reads $U = \frac{1}{2} m (v_1^2 - v^2)$. It appears at a glance that the factor in

parenthesis, correctly expressed, is "the difference of the squares of the velocities." I am inclined to think that probably the translator is responsible for this inaccurate paraphrase, but I am unable to say so, since the French original is not within my reach. However, I do not understand how Mr. Beard could allow himself to be tripped, with the formula plainly before his eyes. By making use of this formula, we derive the work of acceleration of the constant force mf as follows:

In the first second, $U_1 = \frac{1}{2} m(f^2 - 0^2) = \frac{1}{2} mf^2$. In the second second, $U_2 = \frac{1}{2} m[(2f)^2 - f^2] = \frac{1}{2} m \times 3f^2$. In the n th second, $U_n = \frac{1}{2} m[(nf)^2 - (n-1)^2f^2] = \frac{1}{2} m(2n-1)f^2$.

These results show that the work in the first second is $\frac{1}{2} mf^2$ and that the work in any second exceeds the work in the preceding second by mf^2 .

We can get the same results in another way, namely, when we remember that the work of a force is the force multiplied with the distance through which it is exerted. These products are the factors written in the order in which they are given above:

For the first second, $U_1 = mf \times \frac{f+0}{2}$. For the second second,

$U_2 = mf \times \frac{2f+f}{2}$. For the n th second, $U_n = mf \times \frac{nf+(n-1)f}{2}$.

The work of acceleration is a different one for every second. It cannot be given generally for a second.

Mr. Beard's main equation No. 1 (No. 2 is No. 1 divided by p) has been framed under the above misconception; its general form

$U = \frac{1}{2} mf \times f_1$ has been obtained by substituting $m_1 f_1 = m \times f$ in equation $U = \frac{1}{2} m_1 f_1^2$, it expresses the work of the force m accelerating the mass m_1 in the first second—not in any second. By $m_1 = \frac{pa}{Kq}$ Mr. Beard has tried to represent the mass correspond-

ing to the resistance. To show that and why $\frac{pa}{K}$ does not express the resistance, as I have stated in my No. 4, would take up too much space; but I repeat that $\frac{pa}{K}$ is not the resistance, and introduced as such, it is another distinct element of error in equation No. 1.

When equation 1 and 2 are wrong, any result obtained by combining either with any other equation must necessarily also be wrong. In this manner Mr. Beard has arrived at his " q varying as $\sqrt[n]{n^4}$, and his p varying as $\sqrt[n]{n^8}$."

Mr. Beard has offered no comment on my No. 8. I urge him to read it over again carefully, and in the face of the above disclosure of his errors, I trust he will see the truth of my statements there, and will acknowledge that if $U = F \times \frac{f_1}{2}$, then, according

to the definition of "work," $\frac{f_1}{2}$ must be the distance through which the force F is exerted. As the equation stands, both F and $\frac{f_1}{2}$ are unknown; we only know that their product must be equal to Qp ; we require another equation, to solve the problem.

Mr. Beard's other equation is $\frac{f_1}{2} = \frac{1}{2} \frac{KWV_p^2}{pa\rho}$, which, however, cannot express the distance through which the force is exerted in a second as has been shown and will be further shown, when I shall come to discuss the "fundamental error" in Mr. Beard's theory.

In reply to Mr. Beard's comment on my No. 11, I am free to admit that the efficiency I introduced is a pure assumption. I stated it to be assumed, without giving any reason for my choice. Of course I had a reason. I know, for a fact, that his old formula for K was wrong in principle, and since he does not show the deduction of his present one (equation 4), I have not examined it closer. I am quite skeptical of it, however, as I actually do not believe that such high efficiencies can be attained. The fan actually works as a compressor, and I cannot see how it can attain a higher efficiency than is the rule with the most improved compressors built for that special purpose. I think 0.70 fully as high as can be expected; but to please Mr. Beard, I will also state the result of a rational solution of the example, using his calculated efficiency $K = 0.8392$. With this efficiency the fan would deliver 200,000 cubic feet against a pressure of 6 inches water gauge at about 150 revolutions, and at 100 revolutions it would not deliver anything against that same pressure—in fact, it could not generate that pressure. It could, at 100 revolutions, deliver 200,000 cubic feet against about 2.85" W. G.

In conclusion, I will demonstrate the "fundamental error" in Mr. Beard's theory. I might briefly say: *The work of the fan is not a work of acceleration, because it is work against resistance.*

Ganot says: "When work is being done, the physical part of the process consists solely in producing or changing motion, or in keeping up motion in opposition to resistance, or in a combination of these actions.

"When a ship is sailing at a uniform speed, the force exerted on it by the wind causes no change in its motion, but simply prevents such a change being produced by the resistance of the water; or when a railway train is running with uniform velocity, the force of the engine does not change, but only maintains its motion in opposition to the forces, such as friction and the resistance of the air, which tend to destroy it."

The case of air circulation through a mine is exactly analogous to these two examples.

When a body of air is moving through a mine with uniform velocity (this is the case when a constant quantity of air enters and leaves the mine every unit of time) the centrifugal force developed by the air rotated in the fan does not change, but only maintains the motion of that body of air through the mine. It simply prevents a change being produced by the resistance of the mine; hence the work of the centrifugal force is work against resistance.

The centrifugal force, in doing its work, is exerted through a distance identical with the radial velocity of the air through the "movable ducts" in our air conduit. The "movable ducts" are the fan compartments which the air has to traverse radially at some point in its circuit from the atmosphere back into the atmosphere.

The radial velocity through these "movable ducts" is the quotient $\frac{Q}{a}$, where a , of course, is the cross-sectional area of these ducts.

This constitutes the simple solution of the problem, and I trust it will appeal to the "thoughtful mind" and bring order into "chaos."

Yours truly,
P. J. MARKMANN, C. E.

Chicago, Ill.

Burt Exhaust Head.

The construction of the Burt exhaust head is well shown in the accompanying figure. These heads, when attached to the exhaust pipe of a boiler system, prevent the escape of oil and wet steam, and thus prevent injury to adjoining property and disfigurement and the rotting of one's own premises, besides saving of water, as the same water can be used over and over again. This condensed water will be free from sediment and impurities, and the fact that it economizes water recommends this device strongly to many mines where the item of water economy is a most important one.

The Burt exhaust head has perpendicular sides instead of conical ones, thus giving it a greater inside area, which area is also not lessened by inside baffle plates, diaphragms, or scrap metal. The head is made of extra-heavy iron, riveted and soldered, and all joints, seams, and attachments are water-tight. The head cannot overload nor blow up, and is covered with anti-rust paint.

The steam going through the exhaust pipe strikes the cone immediately over the mouth of the pipe which separates the steam into fine particles, thus condensing some of the vapor. A greater part of the steam rises up to the small projection extending around the top of the head, where it is held for an instant, and during this time drops of water and oil fall down between the double walls and out through the drip below.

This device is made by the Burt Mfg. Co., of Akron, Ohio, which has 10 years' experience back of it in the manufacture of oil filters and similar steam appliances, rendering its guarantee of particular value.

C. B. Finley, general manager of the Soddy, Tenn., Coal Co., who for a number of years has been in charge of the mining and coke making at Soddy mines, has resigned to accept a similar position with a Louisville, Ky., mining company. He is succeeded by Mr. Wigton, of Pennsylvania.

PRIZE CONTEST.

Prizes Given for the Best Answers to Questions Relating to Mining.

For the best answer to each of the following questions, the value of \$1 in any of the books in our book catalogue, or six months' subscription to MINES AND MINERALS.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue, or three months' subscription to MINES AND MINERALS.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to MINES AND MINERALS.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only, and each answer must be numbered to correspond with the question.

Fourth—"Competition Contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Time for receiving answers expires on the first day of the month following publication.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Ninth—In awarding prizes, other things being equal, a carefully written and arranged answer will be given the preference.

Competition Questions for August.

QUES. 604.—*Preservation of Mine Timber*.—What is the action of creosote in the preservation of mine timber? Describe also the manner in which timber is preserved by charring.

QUES. 605.—*Cutting Mine Timber*.—In what season of the year should mine timber be cut, and why? State all the reasons that you know for and against the cutting of mine timber at such time.

QUES. 606.—*Gravity-Plane Haulage*.—Calculate the size of rope required to lower an output of 1,000 tons per day of 10 hours, over an incline 300 yards long. The upper landing is 50 feet of vertical height above the tippie. Draw a sketch also showing the profile of the incline, from the tippie to the upper landing. Calculate the starting and stopping grades at the head and foot of the incline respectively, and the uniform grade of the incline. Assume a rolling friction of $\frac{1}{4}$ of the normal pressure upon the plane, and the weight and capacity of the mine cars as 1,500 and 2,200 pounds, respectively.

QUES. 607.—*Strike and Dip of Seams*.—Give a clear explanation of what you mean by the terms "strike" and "dip" in reference to inclined seams.

QUES. 608.—*Cleats and Bedding Planes in Coal Seams*.—Explain the terms "cleats" and "bedding planes" in reference to coal seams and other stratified deposits. Also, state if there is any fixed relation between the direction of the principal or face cleats and the inclination of the seam.

QUES. 609.—*Surveying, Precautions Necessary When Surveying With Magnetic Needle*.—What precautions are necessary in surveying with the magnetic needle, in presence of iron or where attraction is liable to exist? State by what means such a survey may be made fairly reliable.

QUES. 610.—*Ventilation, Effect of Splitting the Air Current Upon the Speed of a Fan*.—The power remaining the same, what effect will the splitting of the air current into two equal splits have upon the speed of the ventilator? State the reasons for your answer.

QUES. 611.—*Furnace Ventilation; Splitting, Pressure Constant*. The circulation in a certain mine is maintained by means of a furnace at the foot of the upcast, but the quantity of air is insufficient for the thorough ventilation of the mine. If it were possible in this mine to divide the air current into two equal splits, would the quantity of air in circulation be doubled by this means? Give the reasons for your answer.

Answers to Questions Which Appeared in the June and Previous Numbers and for Which Prizes Have Been Awarded.

QUES. 588.—*Loaded Car Derailed*.—A loaded mine car weighing 3,500 pounds has been partially derailed, the rear wheels having left the track, while the forward wheels still remain upon the rail. The length of the car, out to out, is 7 feet; the distance

between the centers of the wheels is 21 inches. What force applied to the end of a 5-foot lever would raise the rear end of the car if the lever has a bite of 2 feet; that is to say, the end of the lever is run 2 feet under the end of the car?

Ans.—The weight of car acting at center of gravity exerts a downward turning moment about the front axle of $3,500 \times \frac{21}{12 \times 2} = 3,062.5$ foot-pounds, to balance which requires a lifting force at end of car of $3,062.5 \div \left(\frac{21}{12 \times 2} + \frac{7}{2} \right) = 700$ pounds. The

reaction of this latter force acting on the lever would produce a downward turning moment about the "heel" of $700 \times 2 = 1,400$ foot-pounds, which is to be overcome by a lifting force P applied 5 feet from "heel," or $5 \times P = 1,400$; whence, $P = 280$ pounds.

A. B. JESSUP, Centralia, Pa.

Second Prize.—CHAS. E. BOWRON, Birmingham, Ala.

QUES. 589.—*Removal of a Body of Gas*.—A large body of gas has been discovered in a number of chambers driven 50 yards to the rise of a gangway. The chambers have been abandoned for some time and their ventilation neglected. Describe the difficulties to be encountered in the removal of this gas, and how the work may be accomplished with the least danger to the men employed in the mine.

Ans.—The difficulties to be encountered in the removal of this gas would be as follows: Owing to there being such a large body, we would have to clear it away block by block, as will be explained; we would also have to repair the headings and restore a proper system of ventilation as we proceeded, which would necessarily make its removal quite tedious and slow.

In proceeding to remove this body of gas, I would select a few experienced, competent men, and equip them with the very best type of safety lamp procurable. If I was foreman, I would take entire charge of the work myself, assisted by my fire boss.

In the removal of a large body of this kind, I would conduct a split of air up outside breast direct from first heading, assuming this to be the main return of the mine. I would conduct air up outside breast to first breast heading or breakthrough by means of the best brattice cloth, or if I did not consider this equal to the occasion, I would erect a board brattice. When I reached first breast heading or breakthrough I would repair it and open it up to its proper size, as in all probability it would be partly or altogether closed if it had been abandoned any length of time; this, of course, would depend upon nature of coal, roof, etc.

After having restored the system of ventilation thus far in outside breast, I would proceed in the same manner in the next breast inside, and so on along the entire group, opening up the headings and restoring a good system of ventilation as I proceeded. After clearing all the breasts to this point, I would then proceed to remove gas from breast up to the next heading in the same manner as before, this time connecting my brattice on the mouth of the first breast heading on the inside, using the same brattice as before, as it would not be needed below. After reaching second breast heading I would open it and repair it same as with first heading. Then I would place a stopping in the first breast heading on outside; this would cause the air current to flow through second breast heading. I would proceed in this manner all along the group of breasts, clearing to second heading or breakthrough.

I would again start in same manner at outside breast and clear to the face which, if worked upon proper system, should have headings along the faces of breasts. I would place stoppings in the headings below, which would cause the air current to sweep the faces of the breasts, thus clearing off all gases immediately.

After clearing them I would keep them free by causing an active current of air to circulate through them.

Second Prize.—WM. S. DAVIS, Edwardsdale, Pa.

QUES. 590.—*Grade of Slant Road*.—Give a short, concise rule by which to determine the percentage of grade of a road in an inclined seam, when the inclination of the seam and the angle that the road makes with the direction of the dip of the seam is given. Illustrate the rule by the calculation of the grade of a road whose bearing is N 87° 30' W, in a seam having an inclination of 43° 20'; the direction of the dip of the seam being N 60° 50' E.

Ans.—In the accompanying diagram let CD = a line on the

full dip of the seam; BC = direction of the dip of the seam; CE = slant road; CA = 100 feet of the horizontal projection of said slant road; α = angle of inclination of seam; β = angle which the slant road makes with the direction of the dip of the seam.

Then we have: In the horizontal right-angled $\triangle ABC$,

$$BC = 100 \cos \beta.$$

In the vertical right-angled $\triangle BCD$,

$$BD = BC \tan \alpha = 100 \cos \beta \tan \alpha.$$

Since $BD = AE$ = percentage of grade of slant road AE = $100 \cos \beta \tan \alpha$.

Hence the rule: To determine the percentage of grade of a road in an inclined seam, multiply the cosine of the angle which the slant road makes with the direction of the dip of the seam by the tangent of the angle of inclination of the seam and the product thus obtained by 100.

To apply this rule to the example, we have

$$\alpha = 43^\circ 20';$$

$$\beta = 62^\circ 50' + 87^\circ 30' = 150^\circ 20'.$$

Hence, percentage of slant road = $100 \cos 150^\circ 20' \tan 43^\circ 20' = 81.978$ per cent.

THEODORE SIMONS, Roseland, B. C.

Second Prize.—A. B. JESSUP, Centralia, Pa.

QUES. 591.—*Rescue of Men in Case of Fire.*—A certain mine is ventilated by means of an exhaust fan placed a short distance to one side of the main hoisting shaft. The hoisting shaft is a large three-compartment shaft, two of these compartments being used for hoisting, and forming the downcast for the entire mine. The third compartment is connected with the exhaust fan mentioned, and furnishes the upcast shaft for the return current of the mine. Built over the hoisting shaft is a large building used as a breaker, containing the machinery for the preparation of the coal for market. At a distance of 400 yards from the present shaft is an old abandoned shaft which was formerly used as the hoisting shaft for this mine. What danger do you consider is imminent in the present arrangement, and what measures would you suggest be adopted in order to facilitate the rescuing of the men in case of a fire occurring in the breaker?

ANS.—Three dangers confront us in this question: First, smothering of the men, in case of fire, unless the fan is stopped; second, danger of an explosion in the mine, in case the fan is stopped; third, danger of being entombed, by the hoisting shaft becoming filled with burnt timbers.

I would clean out the old abandoned shaft and retimber it if necessary; partition it off, so as to have two compartments. One compartment I would have furnished with proper hoisting machinery and connected with the present intake airway. In the other compartment I would have a duplicate fan erected and connected with the present return. I would have doors so hung that by closing a door on the present intake and opening a door on the intake of the abandoned shaft, and also the same on the returns, that the airways of the present shaft would be completely cut off, and the same opened to the abandoned shaft. I would have the fan and hoisting engines ready to start at all times on a few minutes' notice. In case of fire I would close down the present fan and start the one at the abandoned shaft, close the doors on intake and return between hoisting shaft and abandoned shaft, open the doors on intake and return of abandoned shaft. Then the air would travel on the same course, going down, and returning in the abandoned shaft, which would be far enough away from the fire that no heat nor smoke would be drawn to it. I would send competent men down at once to different parts of the mine, and hurry out the men. Also instruct them to come to the abandoned shaft to be hoisted up.

JOHN N. KING, Uniontown, Pa.

Second Prize.—JOHN W. POWELL, Carbonado, Wash.

QUES. 592.—*Starting a Furnace Fire.*—A deep mine has been closed for a long period owing to the prevalence of a strike. The mine is not gaseous, but it is subject to gob fires which produce large quantities of blackdamp. The only means of ventilation is a furnace, which has not been lighted during the period of the strike, and the mine is full of damp to the top of the shaft. Explain what difficulties would be encountered when the mine is again started, and how you would proceed to start ventilation and light the furnace fire.

ANS.—I would induce ventilation in the shaft by means of a steam jet or waterfall. When the shaft was clear of blackdamp I would go down, build a brattice back of the shaft, closing off all the workings. I would then break open a brattice connecting the return. I would keep on using my steam jet or waterfall and bratticing off parts of the mine until I reached the furnace. Then I would be able to light a fire. After the furnace got well heated and was making a good current I would begin opening the brattices and letting out just as much blackdamp as the furnace could take without cooling the fire. I would clean out one district at a time, opening brattices in front and closing up behind until I had all the mine clear.

JOHN N. KING, Uniontown, Pa.

Second Prize.—JOHN VERNER, Oskaloosa, Iowa.

QUES. 594.—*Cleats in Coal Seams.*—Explain what is meant by the "cleats" and "joints" of the coal, in working coal seams, and what effect these have upon the manner of working at the face.

ANS.—In most coal seams, there are vertical cleavages, or planes of separation, which are called cleats or joints. These cleats occur in two directions, about at right angles to each other. In every instance one or the other of the cleats is more pronounced, and these are called "face cleats," while the shorter joints or cleats are called the "ends" or "butt cleats."

The butt cleats, more often called "joints," are short and broken, and intercepted by the face cleats.

The cleats of the coal are an important factor in determining the method of attack or direction of driving the breasts.

According to the character of the cleats of any seam of coal, breasts should be worked "face on," "end on," "half on," "long horn," or "short horn." Working "face on" is advancing the breast in a direction at right angles to the face cleats. Working "end on" is advancing the breasts in a direction parallel to the face cleats or principal cleats of the coal. Working "half on" is advancing the breast in a direction making an angle of 45° with the cleats. Working "long horn" is advancing the breast in a direction making an angle with the principal cleats greater than 45° . When the direction which the breast advances makes an angle of less than 45° with the principal cleats, it is termed "short horn." Each of these methods has its peculiar adaptation to the varied conditions of the coal seam. For example, when the face cleats are free, that is to say, the coal breaks readily along the face cleats, and the coal is reasonably hard, the "long-horn" method should be adopted.

The reason for this is, that when the coal is undercut it will need more support than it gets from the cleats, and hence its weight must be thrown somewhat upon the end cleats.

The angle of the breast will depend upon the hardness of the coal and the freedom of the cleats. When the face cleats are working free, and the coal is very soft, it may be necessary to drive the breast "end on," that is, in a direction parallel to the face cleats.

This method is best adapted to a very heavy roof pressure. If, however, the roof pressure is light, the "short-horn" method is often adopted, in order to assist in breaking the coal. The "face-on" method of working is adopted when the face cleats are not so free or numerous as the butt cleats. A little thought will make the adaptation of these different methods very clear to one who is conversant with conditions of mining at the face.

Unless the coal at the face receives sufficient support, the undercutting or "bearing in" cannot be done thoroughly, or else the labor of "spragging" is increased, as also the risk to the miner.

The adoption of one or the other of these methods also reduces the cost of cutting or "shearing" to a minimum.

Second Prize.—THOS. O'BRIEN, La Salle, Ill.

QUES. 595.—*Size of Sheaves.*—Give a rule for calculating the minimum size of sheaves in rope transmission, when the diameter and kind of material of the rope are given. State what are the stresses upon a rope in passing over a sheave, and how these may be calculated. Assume any load upon the rope and arc of contact of the rope upon the sheave.

[No satisfactory solution has been received.—EDITOR.]

Boilers With Too Much Heating Surface.

An interesting illustration of the well known fact that a boiler can have more heating surface than is good for it, was cited recently by Dr. Coleman Sellers in a lecture before the Franklin Institute. When the first large engines and boilers for the water works of the city of Philadelphia were installed many years ago, it was found, upon test, that the boilers were insufficient for their purpose. Oliver Evans, who had designed the engines, had specified the length of the grate bars and the width of the furnace to be used, as also the length of the boilers, which were of the plain cylinder type; but the wise men of the city government believed that they could do better by making the boilers much longer than he had suggested, and they were so constructed. Upon their failure to do the work, Oliver Evans was sent for in haste to correct the difficulty. His message to those in charge, enforced by his presence afterwards, was that they must cut off 10 feet from the length of each boiler. This seemed a strange proceeding, but he soon explained to them that the extra length which they had added to his prescribed dimensions was acting as a condenser to reconvert steam into water, inasmuch as the heat of the furnace could not extend the whole length of the boilers as they had been built. Upon cutting the boilers down to their proper size so the heat could extend over the whole fire surface, they proved sufficient for their work, and continued to operate as long as this primitive water plant was in existence.

TRADE NOTICES.

The A. Leschen & Sons Rope Co., 920-922 North Main Street, St. Louis, Mo. and 47-49 South Canal Street, Chicago, has recently distributed a very neat souvenir penholder. This is made up to show the patent flattened-strand wire rope made by this company, and known as the Hercules brand.

Fraser & Chalmers, Chicago, have received from the Anaconda Copper Mining Co. orders for a large amount of machinery for their new concentrating plant, which will have a capacity of 4,000 tons per day. This machinery includes 24 heavy pattern 5-foot Huntington centrifugal roller quartz mills, 24 sets of 40 in. $\times$ 16 in. crushing rolls with forged-steel shells, and 24 Blake crushers, sizes 24 in. $\times$ 12 in. and 15 in. $\times$ 9 in.

The Imperial Steel Works, owned and operated by the Japanese Government, has just placed an order for the complete equipment of the plant with Cross oil filters, with the Burt Mfg. Co., of Akron, Ohio. As the Burt Co. were in competition with the best manufacturers of filters in Europe and other American makers, they regard it as a distinct triumph for the Cross filter. The Imperial Steel Works is probably the most important plant of the kind in the kingdom.

The Macomber & Whyte Rope Co. announce that it has purchased the entire interest of Mr. Leschen in the Leschen-Macomber-Whyte Co., and he no longer has any connection with their business nor any authority to act for their company, which will hereafter be known as the Macomber & Whyte Rope Co. The company will continue doing business at the old location, 19 and 21 South Canal Street, Chicago, where it has a large stock of wire rope, the quality of which is well known. The company will continue to carry a complete stock of specialties as heretofore, and all orders in this line will be promptly executed; it will also make a specialty of mine, quarry, and contractors' supplies at the lowest market prices.

The Ericsson Telephone Co., 296 Broadway, New York, have just issued Part 4 of "The Ericsson Series." It contains a diagram of connections for a simple metallic circuit switchboard and some interesting information concerning the number of telephone subscribers in the various large cities of Europe, Africa, and South America. Any one sending his name and address will receive a copy by return mail. The Ericsson transmitters, made in Sweden, are protected by oiled silk, making them especially durable for use in damp places, such as mines. Their transmitters and receivers do not seem to be affected in any way by moisture, heat, or cold, which is not the case with many cheap telephones now on the market.

The *London Times* in its issue of June 8, 1900, devoted considerable space to a description of the E. P. Allis Works, Milwaukee, Wis. The reason for this notice was the fact that this company has recently taken extensive contracts for large engines in England and has thus caused surprise and consternation among the English manufacturers who have hitherto not looked for competition in this line from across the water. To indicate the extent of the plant the writer notes that at the time of his visit to the works there was one order alone for 8 pairs of compound engines of 8,000 horsepower. Another order for 11 sets of engines, aggregating 77,000 horsepower, for the electrical power station which was to supply current for the surface railroads for New York City. At the same time the firm had orders on book for 34 blowing engines. These large orders represented only a part of the work in hand.

It is reported that contracts for building a line of steam railroad for the North Coast & Olanco Valley Railroad Co., recently incorporated, will be let in the early fall. This line will be 40 miles long, and will run from Port Burchard to Eldorado. Mr. Chas. B. Cramp, of Philadelphia, is president and Mr. Chas. S. Putnam, chief engineer. The initial surveys have been completed, and the capital secured for pushing this road to early completion, thus opening up a section of Honduras which should be of great interest to Americans who have been used to thinking of the country more from a mineral standpoint than from an agricultural. Port Burchard, on the north coast of Honduras, is only 5 days out from Philadelphia, which is less time than it takes to go to San Francisco or into the interior of Mexico. The completion of this North Coast & Olanco Valley Railroad will greatly enhance the interests of farming, timber cutting, mining, manufacturing, and colonization.

The Aultman Co., of Canton, Ohio, reports that business is holding up very satisfactorily. Recent orders include a sand-handling system for the foundry of the Massillon Iron & Steel Co., at Massillon, Ohio; two large No. 5 Aultman rock crushers for the Bonnot Co., of Canton, Ohio; one No. 3 Aultman rock crusher

and one car haul for the Page Woven Wire Fence Co., of Monessen, Pa.; one refuse conveyor for the Acker Lumber Co., at Livermore, Ky.; one refuse carrier for the Hall & Lyon Furniture Co., of Waverly, N. Y.; one complete plant for the manufacture of tile and building block for the Beatty Fire Clay Co., of Magnolia, Ohio; one tipple-house equipment for the Indian Run Coal Co., of Canton, Ohio; one complete system of elevating and conveying machinery for handling raw material and finished product at the beet sugar refinery of A. W. Colwell & Co. at Marine City, Mich.; six ingot charging machines for the Wellman-Seaver Engineering Co., of Cleveland, Ohio; and a pulp carrier for the Munroe Falls Paper Co., of Munroe Falls, Ohio.

The Flemington Coal & Coke Co., of Flemington, Taylor County, West Virginia, has installed a complete Morgan-Gardner electric plant consisting of three 150-horsepower Erie boilers; two 150-horsepower Skinner engines; two 100 kilowatt Morgan-Gardner dynamos; and a complete system of haulage, which consists of some seven miles of trolley, two electric locomotives (Morgan-Gardner), and seven mining machines (Morgan-Gardner). Mr. A. L. Simpson, general manager of the Flemington Coal & Coke Co., says: "Our vein is the celebrated Pittsburgh seam, and averages about 9 feet in thickness. So far this machinery seems to be doing very nicely, especially the haulage part of same. As to the chain cutting mining machines, it is a great question whether machines of this type of any manufacture are a benefit in such large veined coal. The miners complain that in consequence of the small amount of space which is left for the coal to drop, after being cut by the machines, that it is almost impossible to mine this coal unless sufficient powder is put into same to blow it all to pieces. In this way the resulting coal runs very high in fine coal and slack, which, according to the claims of the different manufacturers, should be just the reverse. The Morgan-Gardner machines, however, work very nicely and cut well. As this machinery has only been running for a few months, we are not in position at present to state whether we consider electric machinery an advantage or not. It certainly is an advantage in haulage; whether this applies to the cutting of the coal is a question that can only be determined after having given this machinery ample trial."

The Northern Pacific Railway Co. has specified Bethlehem nickel-steel for the driving axles and crankpins for 20 locomotives now under contract with the Schenectady Locomotive Works. The Bethlehem Steel Co. reports that the list of railroads using this material is steadily growing, but calls attention to the fact that those wishing to specify it for locomotive forgings should be careful to designate it as Bethlehem nickel-steel, as the reputation gained by it has resulted in the production of inferior imitations which do not show the same high qualities. The Bethlehem Steel Co. also has in hand the entire equipment of steel shafts and engine forgings which are to go into the new steamer building by the Harlan & Hollingsworth Co., at Wilmington, for the Mallory Line. Also all the shafts and forgings for the 11,000-ton steamer which is to be built by the Union Iron Works, of San Francisco, for account of the American-Hawaiian S. S. Co. In this instance the owners saw fit to specify that all the parts mentioned should be made at the Bethlehem Steel Co. plant, a most gratifying testimony to the good effect of the campaign which has been carried on in favor of a higher standard of material and workmanship in such important features of marine construction. The city engineer of Chicago recently placed with the Bethlehem Steel Co. an order for a hollow-forged shaft to replace a breakdown in the North Side pumping station at that city. The new shaft, which measured 13 feet 8½ inches in length, 19 inches in diameter, and weighed close to 10,000 pounds, was booked on May 30, and, under special emergency instructions, was hollow-forged, annealed, and rough-machined in time to go forward June 9.

PERSONALS.

Mr. Benedict Crowell, of the firm of Crowell & Peck, has recently been in Virginia, examining mining property near Richmond.

The Campbell Coal & Coke Co., of Woody, Tenn., has recently purchased 4,000 acres of land in Cumberland County, Tenn. This tract of land is underlaid by two 5-foot veins of coal, one is a steam and domestic block coal, and the other steam and coking coal. A large force of men is at work developing the mines, and the company expects to ship 1,000 tons per day by December next. The officials of the company are: R. O. Campbell, president; J. B. Campbell, secretary and treasurer, Atlanta, Ga.; and A. W. Schenck, manager, Woody, Tenn.

ELECTRICITY IN MINING.

Principles Governing the Calculation, Construction, and Operation of Electrical Installations.

Dynamos and Motors—Speed Regulation of Motors—Alternating-Current Dynamos—Alternating-Current Motors—Induction Motors—Transformers.

Written for MINES AND MINERALS, by R. B. Williamson.

(Begun in May Issue.)

Speed Regulation of Motors.—The torque of a motor depends upon the current; that is, for a given current, the torque will be the same whatever may be the speed, provided the field strength remains the same. The speed at which the armature runs is a matter of E. M. F. only; that is, with a given current the speed will be proportional to the applied E. M. F., or, more strictly, the counter E. M. F., other conditions remaining the same.

It has been shown that the torque will automatically regulate itself for changes in the load. The speed, however, may be varied by varying the applied E. M. F. or the strength of the field. A change in speed may or may not result in a change in the torque required, depending on the character of the work done by the motor.

The simplest way to vary the applied E. M. F. is to insert a resistance, in series with the armature, similar to the starting resistance. By varying this resistance the applied E. M. F. at the terminals of the motor is also varied, although the E. M. F. of the mains remains constant. It is evident that the energy represented by the product of the current and the drop through the resistance is converted into heat, and is thereby wasted; therefore, for great variations in speed this method is not economical, though often very convenient.

The applied E. M. F. may also be varied by varying the E. M. F. of the generator supplying the current, but this can only be done where a single generator is supplying a single motor or several motors, whose speed must all be varied at the same time; so that this method is only used in special cases.

If the strength of the field is changed the speed necessary to give a certain counter E. M. F. will also be changed, which gives a convenient method of varying the speed. If the strength of the field is lessened the speed will increase, and if the field is strengthened the speed will decrease. With shunt motors the field may be weakened by inserting a suitable resistance in the field circuit, as in shunt dynamos; with series motors the same result may be obtained by cutting out some of the turns of the field coils or by placing a suitable resistance in parallel with the field coils.

This method of regulation is also of limited range, since it is not economical to maintain the strength of the field much above or below a certain density. The resistance method described above being rather more simple, it is generally used. For special cases, such as street-railroad work, various special combinations of the above methods of regulation are used.

One of the most common of these is known as the series-parallel method, and is the method of regulation generally used at present for operating street cars. This method is equivalent to the method of cutting down the speed by reducing the E. M. F. applied to the motor and is only applicable where at least two motors are used. It is also used, to some extent, in haulage plants. When a low speed is desired or when the car is to be

FIG. 16.

FIG. 17.

and each motor runs at full speed because it gets the full line pressure. In practice, starting resistances are used in connection with the above to make the starting smooth but the two running positions are as shown, the motors being connected in series in the one case and in parallel in the other.

Connections for Continuous-Current Motors.—Fig. 18 shows the manner in which a shunt motor is connected to the terminals + and - of the circuit. It will be seen that the current through the shunt field does not pass through the resistance R which is connected in the armature circuit. This is necessary, since to

FIG. 20.

FIG. 21.

keep the field strength constant the full difference of potential must be maintained between the terminals of the field coil, which would not be the case if the rheostat were included in the field circuit, for then the difference of potential would be only that existing between the brushes + B and - B . As on starting the motor this difference of potential is small, only a small current would flow through the field coils, which would generate such a weak field that an excessive current would be required to furnish the necessary torque for starting the motor.

When connected as shown, however, the field is brought up to its full strength before any current passes through the armature, so this difficulty does not arise. Since in a series motor the same current flows through both armature and field coils, the starting resistance may be placed in any part of the circuit. The diagram in Fig. 19 illustrates one method of connecting a series motor to the line terminals + and -; here the starting or regulating resistance R is placed between the - line terminal and the brush - B of the motor. To reverse the direction of rotation of a motor it is necessary to reverse either the direction of the field or the direction of the current through the armature. It is usual to reverse the direction of the current in the armature, a switch being used to make the necessary changes in the connections.

Fig. 20 shows the connections of one form of reversing switch. Two metal bars B and B_1 are pivoted at the points T and T_1 ; one is extended and supplied with a handle H , and the two bars are joined together by a link L of some insulating material, such as fiber. Three contact pieces a , b , and c are arranged on the base of the switch so that the free ends of the bars B and B_1 may rest either on a and b , as shown by the full lines, or on b and c , as shown by the dotted lines. The line is connected to the terminals T and T_1 , and the motor armature between a and b , or vice versa, a and c being connected together.

When the switch is in the position shown by the full lines, T is connected to a by the bar B , and T_1 to b by the bar B_1 . If the switch is thrown by means of the handle H into the position indicated by the dotted lines, T is connected to b by the bar B , and T_1 to a by the bar B_1 , and the connection between c and a . The direction of the current through the motor armature, or whatever circuit is connected between a and b , is thus reversed.

In order to reverse only the current in the armature, the reversing switch must be placed in the armature circuit only. Fig. 21 represents the connection for a reversing-shunt motor (a) and a reversing-series motor (b); + and - are the line terminals; R , the starting resistance; B and B_1 the brushes of the motor, and F , the field coil of the motor. Some manufacturers combine the starting resistance and reversing switch in one piece of apparatus.

In connecting up motors some form of main switch is used to entirely disconnect the motor from the line when it is not in use.

To prevent an excessive current from flowing through the motor circuit from any cause, short strips of an easily melted metal, known as fuses, mounted on suitable terminals, known as fuse boxes, are placed in the circuit. These fuses are made of such a sectional area that a current greater than the normal heats them to such an extent that they melt, thereby breaking the circuit and preventing damage to the motor from an excessive current. The length of fuse should be proportioned to the voltage of the circuit, a high voltage requiring longer fuses than a low voltage, in order to prevent an arc being maintained across the terminals when the fuse melts.

If desired, measuring instruments (ammeter and voltmeter) may be connected in the motor circuit, so that the condition of the load on the motor may be observed while it is in operation. All these appliances, regulating resistance, reversing switch, fuses, instruments, etc., are placed inside the main switch; that is, the

current must pass through the main switch before coming to any of these appliances, so that opening the main switch entirely disconnects them from the circuit, when they may be handled without fear of shocks.

ALTERNATING-CURRENT DYNAMOS.

An alternating-current dynamo is one that generates a current which periodically reverses its direction of flow. It was shown in connection with Fig. 10 that an armature provided simply with collector rings produced an alternating current in the outside circuit. This current may be represented by a curve such as that shown in Fig. 22. The complete set of values that the current or E. M. F. passes through repeatedly is known as a *cycle*. For example, the values passed through during the interval of time represented by the distance *ac* would constitute a cycle. The set of values passed through during the interval *ab* is known as an alternation. An alternation is, therefore, half a cycle. The number of cycles passed through per second is known as the *frequency* of the current or E. M. F.

Alternating-current dynamos are now largely used both for lighting and power transmission, especially when the transmission is over long distances. The reason that the alternating current is specially suitable for long distance work is that it may be readily transformed from one pressure to another. We have already seen that in order to keep down the amount of copper in the line a high line pressure must be used. Pressures much over 500 or 600 volts cannot be readily generated with direct-current machines owing to the troubles that are likely to arise due to sparking at the commutator. On the other hand, an alternator requires no commutator or even collecting rings if the armature is made stationary and the field revolving, as is frequently done. Alternators are now built that generate as high as 8,000 or 10,000 volts directly. If a still higher pressure is required on the line it can be easily obtained by the use of transformers, to be explained later. It is thus seen that where power is to be carried over long distances the alternating current is indispensable.

Alternating-current dynamos, like direct-current machines, consist of two main parts, i. e., the field and armature. Either of these parts may be the revolving member, and in many modern machines the armature or the part in which the current is induced is the revolving member. Fig. 23 shows a typical alternator of the belt-driven type, having a revolving armature. It is not unlike a direct-current machine as regards its general appearance. The number of poles is usually large, in order to secure the required frequency without running the machine at a high rate of speed. The frequencies met with in practice vary all the way from 25 to 150. The higher frequencies are, however, passing out of use, and at present a frequency of 60 is very common. This frequency is well adapted both for power and lighting purposes. When machines are used almost entirely for lighting work, frequencies of 125 or higher may be used. The frequency of any machine may be readily determined when the number of poles and the speed is known, as follows:

$$\text{Frequency} = \frac{\text{number of poles}}{2} \times \frac{\text{rev. per min.}}{60}.$$

For example, if an 8-pole alternator were run at a speed of 900 R. P. M. the frequency would be

$$f = \frac{8}{2} \times \frac{900}{60} = 60 \text{ cycles per second.}$$

Alternators may be divided into the two following classes: (a) Single-phase alternators; (b) Multiphase alternators.

(a) *Single-phase Alternators.*—These machines are so called because they generate a single alternating current (as represented by the curve shown in Fig. 22). The armature is provided with a single winding and the two terminals are brought out to collector rings, as previously described. Single-phase machines have been largely used in the past for lighting work, but they are gradually being replaced by multiphase machines because the single-phase machines are not well suited for the operation of alternating-current motors.

(b) *Multiphase Alternators.*—These machines are so called because they deliver two or more alternating currents that differ in phase, i. e., when one current is, say, at its maximum value the other currents are at some other value. This is accomplished by providing the armature with two or more distinct windings which are displaced relatively to each other on the armature. One set of windings, therefore, comes under the poles at a later instant than the winding ahead of it, and the current in its winding comes to its maximum value at a later instant than the current in the first winding. In practice, the two types of multiphase alternator most commonly used are (1) two-phase alternators, (2) three-phase alternators.

Two-phase alternators are machines that deliver two alternating currents that differ in phase by one-quarter of a complete cycle, i. e., when the current in one circuit is at its maximum value the current in the other circuit is passing through its zero value. By tapping four equidistant points of a regular ring armature, as shown in Fig. 24, and connecting these points to four collector rings, a simple two-pole two-phase alternator is obtained. One circuit connects to rings 1 and 1', the other circuit connects to rings 2 and 2'. It is easily seen from the figure that when the part of the winding connected to one pair of rings is in its position of maximum action, the E. M. F. in the other coils is zero, thus giving two currents in the two different circuits that differ in phase by one-quarter of a cycle or one-half an alternation.

Three-phase alternators are machines that deliver three currents that differ in phase by one-third of a complete cycle, i. e., when one current is flowing in one direction in one circuit the currents in the other two circuits are one-half as great and are flowing in the opposite direction. By tapping three equidistant points of a ring winding, as shown in Fig. 25, a simple three-phase two-pole alternator will be obtained. Three mains lead from the collecting rings.

In order to have three distinct circuits it would ordinarily be necessary to have six collecting rings and six circuits, but this is not necessary in a three-phase machine if the load is balanced in the three different circuits, because one wire can be made to act alternately for the return of the other two.

Uses of Multiphase Alternators.—Multiphase alternators are coming largely into use, because, by using them, alternating-current motors can be readily operated. By using multiphase machines, motors can be operated that will start from rest under load, whereas with single-phase machines the motor has to be brought up to speed from some outside source of power before it can be made to run. For this reason such machines are used for the operation of modern power-transmission plants. As far as

FIG. 22.

FIG. 23.

FIG. 24.

FIG. 25.

FIG. 26.

FIG. 27.

FIG. 28.

the general appearance of three-phase machines goes they are similar to ordinary single-phase alternators, the only difference being in the armature winding and the larger number of collector rings. The multiphase alternator is also adapted for the operation of lights, so that by using these machines both lights and motors may be operated from the same plant. They are well adapted for power-transmission purposes in mines, especially for the operation of pumping and hoisting machinery, because the motors operated by them are very simple in construction and therefore are not liable to get out of order.

ALTERNATING-CURRENT MOTORS.

Alternating-current motors may be divided into two general classes: (a) Synchronous motors; (b) Induction motors.

(a) *Synchronous motors* are almost identical so far as construction goes with the corresponding alternator. For example, a two-phase synchronous motor would be constructed in the same way as a two-phase alternator. They are called synchronous motors because they always run in synchronism, or in step with, the alternator driving them. This means that the motor runs at the same frequency as the alternator, and if the motor had the same number of poles as the alternator it would run at the same speed no matter what load it might be carrying. This type of motor has many good points, and is especially well suited to cases where the amounts of power to be transmitted are comparatively large and where the motor does not have to be started and stopped frequently. Multiphase synchronous motors will start up from rest and will run up to synchronous speed without aid from any outside source. They will not, however, start with a strong starting torque or effort, and will not, therefore, start up under load and cannot be used in places where a strong starting effort is required. For this reason synchronous motors are not suitable for intermittent work.

(b) *Induction motors* are so called because the current is induced in the armature instead of being led into it from some outside source. Fig. 28 shows a typical induction motor. There are two essential parts in these machines, viz., the field into which multiphase currents are led from the line, and the arm-

FIG. 30.

to the line, is stationary. Fig. 27 shows the construction of the stationary member or field. This consists of a number of iron laminations built up to form a core and provided with slots around the inner periphery. The form-wound coils constituting the field winding are placed in these slots and connected to the mains. This winding is arranged in the same way as the armature winding of a multiphase alternator. When the alternating currents differing in phase are sent through the winding, magnetic poles are formed at equidistant points around the periphery of the field, and the constant changing of the currents causes these poles to shift around the ring, thus setting up what is known as a revolving magnetic field. This armature, Fig. 28, consists of a laminated iron core provided with a number of slots, in each of which is placed a heavy copper bar *b*. The ends of these bars are all connected together by two heavy short-circuiting rings *r, r* running around each end of the armature. The bars and end rings thus form a number of closed circuits. When such an armature is placed in the revolving field the magnetism will cut across the armature conductors, inducing E. M. F.'s in them, and since the conductors are joined up into closed circuits, currents will flow in them. These currents will react on the field, and the armature will be forced to revolve. Such an armature will not run exactly in synchronism, because if it did it would revolve just as fast as the magnetic field, and there would be no cutting of lines of force. The speed drops slightly from no load to full load, but if the motor is well designed this falling off in speed is slight.

Induction motors possess many advantages for mine work. One of the chief of these is the absence of the commutator or any kind of sliding contacts whatever. Such motors can, therefore, operate with absolutely no sparking—a desirable feature for mine work. The motors are also very simple in construction, and are, therefore, not liable to get out of order. They

FIG. 29.

have an additional advantage over the synchronous motor in that they start up with a strong starting effort, and, in fact, behave in most respects like any good shunt-wound direct-current motor. They are used for all kinds of stationary work, such as pumping, hoisting, etc., but have not been used to any great extent for haulage purposes. When these motors are used for purposes where a variable speed is required, it is customary to provide the armature with a winding similar to that of the field and bring out the terminals to collecting rings so that resistance may be inserted in the armature circuit.

TRANSFORMERS.

One of the principal reasons for the fact that continuous current is giving place so largely to alternating current is the ease with which the latter may be transmitted over long lines at high voltages, and then be transformed at the receiving end to currents of lower pressure suitable for operating lights, motors, or other devices. If power is to be transmitted over long distances, it is absolutely necessary that high line pressures be employed, in order to make the cost of the conductors reasonably low. Reference has already been made to the use of transformers for changing an alternating current from a higher to a lower pressure, or, vice versa, with a corresponding change in current. Transformers used for raising the voltage are known as *step-up* transformers; those used for lowering the pressure are known as *step-down* transformers.

The transformer consists of a laminated iron core upon which two coils of wire are wound. These coils are entirely distinct, having no connection with each other. One of these coils, called the *primary*, is connected to the mains; the other coil, called the *secondary*, is connected to the circuit to which current is delivered. Fig. 29 shows the arrangement of coils and core for a common type of transformer. The secondary coil is wound in two parts *SS'*, and the primary coil, also in two parts *PP'* is placed over the secondary. *C* is the core built up of thin iron plates. Fig. 30 shows a weatherproof cast-iron case for this transformer. When a current is sent through the primary it sets up a magnetism in the core which rapidly alternates with the changes in the current. This changing magnetism sets up an alternating

FIG. 31.

E. M. F. in the secondary, and this secondary E. M. F. depends upon the number of turns in the secondary coil. If the secondary turns are greater than the primary, the secondary E. M. F. will be higher

FIG. 32.

than that of the primary. The relation between the primary E. M. F. and secondary E. M. F. is given by the following:

$$\text{Secondary E. M. F.} = \text{primary E. M. F.} \times \frac{\text{secondary turns}}{\text{primary turns}};$$

or,

$$\text{secondary E. M. F.} = \frac{\text{primary E. M. F.}}{\frac{\text{primary turns}}{\text{secondary turns}}}$$

The ratio $\frac{\text{primary turns}}{\text{secondary turns}}$ is known as the ratio of transformation of the transformer. For example, if a transformer had 1,200 primary turns and 60 secondary turns its ratio of transformation would be 20 to 1, and the secondary voltage would be one-twentieth that of the primary. Transformers are made for a number of different ratios of transformation, the more common ones being 10 to 1 or 20 to 1. Of course a transformer never gives out quite as much power from the secondary as it takes in from the primary mains, because there is always some loss in the iron core and in the wire making up the coils. The efficiency of transformers is, however, high, reaching as high as 97 per cent. or 98 per cent. in the larger sizes. Transformers are always connected in parallel across the mains, and, if they are well designed, will furnish a very nearly constant secondary pressure at all loads when furnished with a constant primary pressure. Fig. 31 shows transformers connected on a single-phase circuit; Fig. 32 shows the connection for a two-phase circuit; and Fig. 33 shows one method of connection for a three-phase circuit.

Transformers are usually set up in moisture-proof and fire-proof iron cases on poles or attached to the outside of buildings. Sometimes they are placed in subcellars or vaults within the buildings. The cases are sometimes filled with oil to ensure good insulation.

FIG. 33.

(The End.)

ARGO OR NEWHOUSE TUNNEL.

The Purposes for Which It Is Being Driven and the Method of Driving.

A Comparison of the Length and the Methods of Driving This Tunnel and Some of the Other Large Tunnels Which Have Been Driven in Past Times.

Written for MINES AND MINERALS, by Prof. Arthur Lakes.

By far the largest and most important of the tunnel enterprises in Colorado is the Newhouse or Argo tunnel at Idaho Springs. This tunnel, which has been many years in progress since its inception, has at last borne fruit, and within the past few weeks has come into prominent notice by a remarkable strike it has made at the end of over 1½ miles of tunnel work. We visited the tunnel a few days after the strike and found its general development, though vastly lengthened, but little differing in detail from when we examined it in 1895. A big tunnel once begun is, as a rule, carried on with monotonous regularity and similarity of detail to near its completion.

As the Newhouse tunnel is one of the greatest tunnel enterprises of the West, and we may say, of the world, especially from a miner's point of view, it is interesting to compare it with others in both hemispheres, that have preceded it, and to compare notes as to the rapidity of progress and facilities derived from inventions which make the modern tunnel such a very different enterprise from those of past years.

Amongst great tunnel enterprises we may mention the Nequehoning, Musconetcong, Hoosac, and Sutor tunnels, in America, and the Mt. Ceniz and St. Gothard, in Europe. The Rothshönberger Stollen tunnel, in Saxony, is an example of old-style work and of German perseverance, and the Sutor, of more modern appliances.

The Sutor tunnel is so well known to all American mining men that we shall only touch upon a few points so far as they have a bearing on the Newhouse.

The tunnel is in the Washoe Range, Storey County, Nevada. It was early considered that it would be an advisable thing to tap the lode at a great depth by tunnel. Before the tunnel everything was raised to the surface by steam power.

In 1860, A. Sutor conceived the plan of driving a deep tunnel to the Comstock lode. In 1865 the Legislature granted a franchise of right of way. The other companies working on the Comstock agreed to pay a toll of \$2 per ton on every ton of pay ore after the completion of the tunnel. The legal rights given the tunnel are interesting for comparison with those which have lately been formulated on tunnel enterprises.

Congress, by the Sutor Tunnel Act, gave Sutor:

1. The right of way to run a tunnel seven miles long to and beyond the Comstock lode, and a north and south drift on this vein and all others found on the line of tunnel.
2. The right to sink shafts on the line of the tunnel, and to purchase public land in connection with the tunnel at \$1.25 per acre.
3. The right of acquiring at \$5 per acre all veins occurring inside a distance of 2,000 feet from the tunnel, except those already in possession of other parties.
4. To levy a royalty on mine owners in consideration of the drainage and other advantages on the completion of the tunnel.

Between 1860 and 1878 the Comstock produced \$291,341,026. Its total product up to date is over \$325,000,000.

Sutor's scheme was to make the tunnel a main artery from which branches should extend throughout the entire mining district, which has a width of 8,000 feet and a length of five to seven miles. This was to be crosscut at intervals and recross-

cut, thus finding all bodies of ore in the district, also to supply cheap transportation, drainage, and other facilities. The tunnel, starting from Carson Valley, penetrates the rock 20,000 feet and strikes the lode near the middle of its productive portion, 1,900 feet below its highest outcrop.

The rocks encountered were hornblende, andesite, augite, andesite diabase, diorite. The greatest depth reached by shaft was 3,000 feet. Intense heat prevails in the lower levels and much hot water is found there. In July, 1878, connection was made with the Savage vein and mine at 20,000 feet, and a strong draft set in at once; in September, 1878, another mining drift was encountered, and in October a third. In January, 1879, connection was made with four more shafts. In September, 1872, the first attempt at machine drilling was made, and 542 feet of holes drilled in 30 days by the Burleigh drill. Dynamite was first used in 1870. Six drills were used in the face.

The Sutor as typical of the introduction of the new style and appliances, and the Rothshönberger Stollen, of the old style, are worthy of comparison.

The latter was commenced in Saxony, in 1844, and opened in 1877. All but the last few hundred feet were driven by hand labor without any of the modern appliances. The best average was 279 feet per month. The length is 42,366 feet. The deepest point reached was 308 feet below the surface. With all its branches completed there will be about 31 miles of tunneling. The longest tunnel in the world. The cost up to 1874 was \$1,500,000 or about \$51 per running meter. This long tunnel gains a depth of only 308 feet below the Anna mine adit, and

connections with other mines give a drainage of only 499 feet. The object of this tunnel is the same as that of the Sutor, which is five miles long, and meets the workings nearly 2,000 feet below the surface. If the economical Germans can spend so much money and time in making an adit 30 miles long for the sake of gaining a depth of 300 feet drainage, it is evident that the days of deep tunnels are not over.

In Utah they have driven a tunnel four miles long to drain by a few hundred feet the celebrated Ontario silver mine, and this through the hardest limestone and quartzite.

The Argo or Newhouse Tunnel.—Idaho Springs is both a watering place and a mining town on the South Fork of Clear Creek. Central is a strictly mining town, high in the mountains, five miles north of Idaho Springs. These two camps are the center of a little strip of country four miles by five, which since 1859 has produced over \$80,000,000, principally gold.

Around Central there are 10 mines which have passed the million-dollar mark. There are 5 to 10 shafts reaching a depth of from 1,200 to 2,200 feet, and 20 mines ranging in depth from 700 to 1,200 feet. In consequence of the excessive cost of pumping and hoisting, the working of some of these mines has been temporarily abandoned. In view of the fact that Idaho Springs, on the main stream of Clear Creek, four miles from Central, is 1,100 feet lower in altitude, it was simultaneously determined by various parties to run long tunnels at a slight grade, practically from the line of railroad below and above Idaho Springs, in the direction of the rich mines, and by tapping them from below not only to drain them automatically but to take out the ore by natural gravity to the railroad tracks. The first and foremost of these is the Newhouse tunnel, whose total length will be 4½ miles.

A poor dirty stream supplies water to the mines and mills of Central, quite inadequate to their wants, whilst the South Fork, at Idaho Springs, is a powerful stream throughout the year.

On the southern face of this region, ascending from Idaho Springs, the surface is steep and mountainous, diversified by ravines and culminating on the summit of Pewabic Mountain, several thousand feet above the river below. From this a fine view both of the mines of Central and Idaho Springs is obtained. From summit to base the mountain slope is dotted both with mine openings and prospect holes, following certain roughly parallel lines indicating the outcrop of a series of parallel fissure veins. These veins the Newhouse will cut at considerable depth at right angles to their general strike or direction; the greatest depth

TIMBERING NEWHOUSE TUNNEL.

attained will be 3,000 feet. The tunnel is 12 feet wide by 12 feet high, and is now in 8,500 feet.

From the top of this mountain, forming the dividing ridge between the two mining districts, we look north on a country of rolling hills and open valleys, continuing as far as the Cañon of

NEVADAVILLE. NEAR CENTRAL, CAL.

the North Fork, along whose banks are strung out the mining towns of Nevadaville, Central, and Black Hawk; towns whose streets are undermined by mining tunnels and shafts, while the noise of ore crushing mills, ill supplied with water fills the air, indicating active mining in the vicinity. This section of Gilpin is even more honeycombed with mines and prospects, and dotted with mining dumps and shaft houses than the vicinity of Idaho Springs, impressing one with the fact that the whole region is underlaid by a vast network of gold and silver veins, many of which have produced ore continuously for the past 30 years.

The geology is simple, consisting of a country rock of mica schist and gneiss, traversed by numerous dikes of porphyry and pegmatitic veins. In the general uplift a series of more or less parallel fissures were formed, extending some miles across country, and descending to depths far below the reach of mining operations. These fissures were filled with quartz and feldspar veins, carrying certain amounts of gold and silver ores, principally the former.

The experience of 30 years has shown in the deepest mines, such as the California, which is over 2,200 feet deep, that richness rather increases with depth than otherwise, and that both increase in size and value in depth has been remarkably shown in the late strike on what is believed to be the "Gem" or "mother vein" in the Newhouse tunnel itself.

The great number of mineral veins in this region is shown by the section of those already well known and developed veins that lie in the pathway of this tunnel. There are 1,400 patented claims in Gilpin County alone, with a large number on the Idaho Springs side. There are doubtless many others concealed by debris and brush. These blind veins will become the property of the Newhouse tunnel in its deep workings. Their development will add to the development of the tunnel.

The Newhouse will undermine, at an average depth of nearly 2,000 feet, a mountain $3\frac{1}{2}$ miles in diameter traversed by an unusual number of parallel fissure veins carrying more or less gold and silver, the richness of many of which has already been satisfactorily proven. The purpose of the tunnel is to discover, crosscut, drain, and operate at greater depths than otherwise feasible, lodes of gold and silver, and to offer working facilities to mines discovered hitherto, and to offer an outlet and milling facilities to all at a minimum cost.

The arrival of the tunnel at or rather beneath the mines will be an enormous help to them, especially in getting rid of the water with which they are at present overburdened. Thus it is estimated that, while 36 leading mines have produced \$53,000,000 they have expended over \$8,000,000 in pumping and sinking 73,000 feet of shafts. One mine for years raised on an average 40

tons of water for every ton of ore and rock. An appalling accident in the Cook and Sleepy Hollow mines, of Central, will illustrate the dangers to be averted by the arrival of the Newhouse tunnel. Sixteen miners lost their lives; the water of one mine, long pent up, breaking into two other mines. The Newhouse drainage tunnel would have prevented this.

The tunnel will cut through virgin ground in an old mining region of wide extent and reputation, a number of lodes yielding pay ore at great depths. It will afford the cheapest method of working these mines. Thousands of tons of low-grade ore, now lying idle in the mines and dumps will be handled at profit by this tunnel subject to its tariff. Enormously expensive machinery, now operated by steam at great cost, will be no longer needed. Great shafts to accommodate pumping and hoisting machinery will be no longer necessary. A natural ventilation and drainage system for the district will be established, subject to tariff, and lucrative to the Argo Co., in connection with drainage already in the Newhouse. Although only a few veins have been cut and none as yet developed, yet a perceptible diminution of water is already experienced in many of the mines on the hill above, and water is pouring down copiously in what is supposed to be the Gem vein just cut. The approach to a vein in the tunnel is generally heralded by a copious supply of water pouring in.

The following notes, descriptive of the construction of the tunnel, were given me by Mr. Walter H. Wiley, engineer in charge:

The tunnel is 12 feet wide by 12 feet high, with double track of 18-inch gauge and a space of 30 inches between tracks. Beneath this central space is a wooden drain, 2 feet wide and 14 inches deep, the top of the drain even with the top of the ties forming a foot path. This box, as the flow of water was at first small, was utilized to convey the foul air out by means of an exhaust fan at the entrance of the tunnel. Since this, and at present, the foul air is carried out by a pipe, 19 inches in diameter, through the medium of a No. 7 Root exhaust blower, with capacity of 12,000 cubic feet per minute, connected with the breast of the tunnel by 19-inch steel air pipe.

The exhaust blower is located in the engine house at the outlet to be described later.

The first 80 feet are timbered with square 10-inch timber, forming an arch overhead. For the rest of the way the rock is so firm and massive that very little timber is required. The rails weigh 30 pounds per yard, and are laid on ties $7\frac{1}{2}$ feet long, which in one side are laid with the end close to the rail to allow room for an open side drain.

The grade is 5 inches in 100 feet. At intervals of about 1,000 feet, short crosscuts are run in the sides of the tunnel, to which the timber men retreat when blasting takes place, and in the one nearest the heading is the battery with which the shots are fired. The character of the rock is gneiss and schist much banded with mica or hornblende, crossed at times by large pegmatitic veins, sometimes passing into mica schist, at others into a very tough, hard black hornblende rock. Several dikes of porphyry have been crossed, and a number of small veins showing mineralization, and in the last few hundred feet several larger mineralized

DUMP AND POWER HOUSE OF NEWHOUSE TUNNEL.

veins, including the last, known as the "big strike" or what is supposed to be the Gem or mother vein. The tunnel is now in 8,500 feet.

The straight line of the tunnel is maintained by a surveyor, who has wooden plugs with screw eyes driven in the exact center line of the roof. By alignment with lamps suspended from these

points, the exact center is determined in the heading every day. This point being determined, the workmen at the face have a vertical central line down the heading and commence work on either side of this. The drilling is done with two 3 inch cylinder Leyner power drills working day shift only. Trimming of dirt is done by the night shift only. The holes are 19 in number, drilled five on either side of the central line, and four or five nearer the sides of the tunnel. The first holes converge inward, and the central core is blasted out first, taking out a wedge-shaped mass of rock.

Drilling is commenced with a short bull drill about 2 feet long, the point 2½ inches diameter; longer drills follow, the point of each of less diameter than the preceding one, drilling a hole shaped like a telescope looking toward the eyepiece. The center cut holes are 8 to 10 feet long, the side ones 6 to 8. Dynamite is used, 100 to 175 pounds each round. The half-pound sticks of dynamite are lowered into the hole as many as 16 sticks at a time, and firmly tamped by a piece of gas pipe with a wooden plug in the end. The 9-foot holes are filled 6 feet deep with dynamite, and the remainder of the hole to the top is filled with cartridges of fine dirt ready prepared. Prior to the tamping the exploder is inserted firmly imbedded in a stick of dynamite. This exploder is a small copper cap about 1 inch long filled with fulminate of mercury. To it are attached two fine copper wires, one negative, the other positive, both thoroughly insulated with a rubber covering. These wires came out of the drill hole at the side of the tamping. The wires for the different holes are united, then one on each side is connected with the main leading wires from the battery. The last 50 feet of the main wire are of a smaller and cheaper kind, and most of this is destroyed at the explosion.

The battery stands safely in a short crosscut some hundreds of feet from the heading, and to this crosscut the men retreat before each explosion. When all are under cover the arm of the battery is raised, rapidly lowered, and all the holes connected are exploded simultaneously. Previous to this the drills are removed to a place of safety. The powder smoke fills the recess and the men wait a few minutes before returning to the heading.

The powder smoke is rapidly sucked out by the indraft of the exhaust fan through the 19-inch pipe. So strong is this draft that a fringe of smoke may be seen hovering on the edge of the pipe, descending it and none of it transgressing the line where the pipe's mouth is. After the center core is cut out, the side rounds are blasted, and then a gang of men immediately begins to clear out the broken rock, which is trammed out to the dump in train loads drawn by mules. In all 21 men are employed, divided into one shift of drill men and two shifts for handling the rock.

On a visit to the tunnel we leave Idaho Springs and walk about half a mile down Clear Creek to the huge dump which occupies several acres on the flat of the creek. A large acreage has been secured for the vast amount of dump matter that will be drawn from the excavation of the tunnel.

We enter the power house, where we see the formidable machinery of the Newhouse tunnel, consisting of two 16 × 16 Norwalk compressors; three 80-horsepower boilers. The No. 7 Root exhaustor is a huge machine, capacity 12,000 cubic feet per minute, connected with the breast by a long steel pipe of 19 inches diameter, carrying the air. The exhaustor has a 50-horsepower direct-connected engine; it can either blow or exhaust by means of valve switches in the pipe. The fan blades of the exhaust weigh 9,000 pounds.

The hot-water heating boiler in the miners' changing room conveys hot water through a circulating system into the powder-warming room, some 50 feet away, keeping powder at even temperature for use. It is heated by return coil of pipes with steam. Five 3-inch drills are used. The blacksmith-shop forge is driven by a waterwheel and blower, using the water which comes from the tunnel. Ore bins are being prepared at the bottom of the dump to carry 1,000 tons of ore; which at present comes from the new strike.

We enter the tunnel on a small Brunton bicycle car moving on the rail. There are larger cars carrying a number of men. We speed rapidly along to the face of the tunnel at a distance of 8,500 feet from the entrance. Here the men are putting in the holes 8 feet deep for the blast, as we have described. Just before

reaching this point we pass under a copious shower of water, descending from the side of the new vein lately struck. The vein is blackened with powder smoke, so we can form little idea of its detail characteristics. Here and there we knock off pieces of compact smelting ore of fine-grained galena and copper pyrite. We are told that the vein, supposed to be the Gem or mother vein of the district, is upwards of 50 feet wide, that streaks of smelting ore are found throughout the mineralized body, and between the streaks of smelting ore are bodies of milling ore. The pay ore is estimated at from 30 to 40 feet in width.

Last week the foot wall was struck, and now the hanging wall is found, showing the vein to be about 50 feet wide, dipping about 70° to the northwest into the mountain.

The Newton mill is now treating the concentrating ore taken out in the crosscutting. In addition to over 100 tons of this mineral, about 15 tons of smelting ore were also marketed. This ranges in several classes of net values of \$50 to \$80 per ton. The mill ore will run \$10 to \$15 a ton, concentrating 4 tons into 1. It being lead, copper, and iron, free from zinc, the system of treating with gigs, screens, and Wilfley tables, makes a saving of every particle of value in which the gold and silver are found.

The present strike is made 2,000 feet below the surface. Work will commence immediately on the vein, the lode will be timbered on both sides and drifted on for 200 feet. Owing to the great width of the ore body it will be a problem how best to handle the vein above, for it is already crumbling. Iron pillars may be used instead of the usual wooden columns. The drift will be at first extended on the hanging wall, leaving the ore body between as a pillar.

The black oxide of copper assays \$20 per ton. In an upper working the average value of smelting ore was \$60 per ton, sometimes \$150 to \$200.

W. E. Renshaw owns the Gem and a number of claims on the line of the tunnel, and in addition is working several others under lease and bond.

The shaft of the Gem extension in the surface was sunk 600 feet, and drifts extended on both sides. From this ground there has been a production up to this time of \$1,000,000. The Main Trunk claim lies on the west, and it is this part of the group where the larger bodies of ore have been cut. It is the intention to raise on the vein at a point 180 feet east of the tunnel line, and at the same time sink a shaft. The strike made in the tunnel means millions additional capital for this section. It has proved the existence of the smelting ore at a depth of 2,300 feet.

The Prevention and Removal of Scale in Steam Boilers.

There is no subject in connection with the use of steam of so much importance as that of the prevention of deterioration of boilers from the injurious effects resulting from an accumulation of scale on the interior surfaces, and from the feedwaters containing chemical ingredients, which attack the iron, producing some one of the numerous forms of corrosion, and to which cause, no doubt, are due many disastrous explosions, entailing great loss of life and property. The Red Seal Boiler Compound, made by the Cherry Chemical Co., 1215 Filbert Street, Philadelphia, Pa., is a chemical preparation that has been used for many years by more than twenty thousand representative establishments throughout the United States and Canada. It is claimed that it neutralizes the acids in feedwaters, and that it prevents and removes scaly deposits, without in any manner injuring the material of the boiler.

This compound is manufactured dry, in the form of a granulated powder, in appearance resembling common brown sugar, and is put in half barrels, barrels, and casks weighing 100 to 1,000 pounds, for the convenience of large and small consumers. It readily dissolves in water, and can therefore be applied in a dry state through the manhole, or in a liquid state by the feed pump. The quantity for an application will depend upon the nature and amount of water evaporated.

The makers claim that when this compound is used honestly and strictly according to the directions, it will never fail to meet the most sanguine expectations of the purchaser, but being composed of chemicals which are harmless to boiler material, its action may require a longer period than would be needed by many other compounds which, while removing the scale, likewise destroy the boiler iron by their corrosive action.

This compound has been endorsed by professional men, by authors of mechanical books, by engineers in charge of works, practical chemists, professional inspectors, and manufacturers having large capital invested in steam boilers. This endorsement, according to the manufacturers, is due to the fact that not a single accident has occurred to any boiler using this compound, although they are to be found in every steam-using locality from Canada to Mexico, and from Maine to the Pacific slope. No stronger recommendation of its merits can be given.

THE METALLURGY OF ZINC.

The Physical Properties—The Chemical Properties. Zinc Ores—Methods of Reducing the Ores.

The Dry Processes—Wet Processes—Electrometallurgical Process—Processes in Which Zinc is Obtained in the Form of an Oxide or Pigment.

Written for MINES AND MINERALS, by H. Van F. Furman E. M.

The production of zinc in the United States has increased enormously in the past 10 years. The production in 1889 was 58,860 short tons, whilst the production in 1898 was 115,399 short tons. The production for 1899 has been estimated at 135,796 tons. The next few years will probably witness a still further increase in the production. In view of these facts a brief résumé of the methods in vogue for the extraction of zinc from its ores may be of interest to the readers of MINES AND MINERALS.

THE PHYSICAL PROPERTIES OF ZINC.

Color and Fracture.—The color of zinc is white, having a bluish-gray tint. It crystallizes in the isometric system. It possesses a high luster on the freshly fractured surface, the nature of the fracture depending upon the temperature at which the fluid metal was cast.

Specific Gravity.—This depends somewhat upon the temperature of the fluid metal at the time of casting and upon the rate of cooling. For ordinary commercially pure zinc it may be considered as 7.15, which is increased to 7.30 by rolling.

Melting Point.—The melting point of zinc is 415°C . Its boiling point is variously stated at from 891°C . to $1,040^{\circ}\text{C}$. Zinc vapor condenses at between 415° and 550°C .

Effect of Impurities.—Commercial zinc generally contains lead, cadmium, iron, and carbon; small quantities of tin, copper, arsenic, and sulphur are sometimes present. Chlorine has been found in some commercial zinc.

Lead renders the metal tender and unfit for rolling. With $1\frac{1}{2}$ per cent. of lead it can be rolled without cracking, but the resulting plates are soft and tender. A greater amount causes the plates to crack, and also causes the film produced in galvanizing to scale off in patches.

Cadmium occurs in most commercial zinc, but as it is more volatile than zinc it is present only in small quantities which have no injurious effect upon the properties of the zinc.

Iron is usually present in small amounts. In fact, in good commercial zinc, the percentage of iron present rarely exceeds 0.18, which small amount does not affect the properties of the metal. Larger amounts render the metal hard and unfit for rolling.

Commercial zinc almost invariably contains small amounts of carbon, which have no influence on the nature of the metal.

Some zincs contain small amounts of tin. If present to the extent of 1 per cent. the metal is brittle and unfit for rolling.

Small quantities of arsenic and antimony are frequently found in commercial zinc, but the small amounts usually encountered have apparently no effect upon the properties of the metal. Sulphur is seldom present. In such minute quantities as have been found it apparently has no effect on the properties of the metal.

Copper is seldom present. When the zinc contains $\frac{1}{2}$ per cent. of copper it becomes harder and brittle, showing cracking and ragged edges on rolling.

THE CHEMICAL PROPERTIES OF ZINC.

Zinc is not affected by dry air at ordinary temperatures. When the air contains moisture and carbonic acid, the surface of the metal is changed (corroded) to hydrated basic zinc carbonate.

Zinc heated in the air to redness (about 500°C .) burns with a light greenish-blue flame to zinc oxide. It decomposes water at a red heat, giving rise to zinc-oxide and hydrogen gas.

Zinc dissolves in most acids. When dissolved in dilute hydrochloric or sulphuric acids, hydrogen gas is evolved. Impure zinc dissolves more rapidly than the pure metal, owing to electrolytic action, and the greater surface which is exposed to the action of the solvent. Aqueous alkaline solutions dissolve zinc with the evolution of hydrogen, but the solvent action of alkalies is slower than that of acids.

Zinc precipitates all of the heavy metals, except iron and nickel, from their solutions in the metallic state. Zinc is not precipitated from its solutions in the metallic state by any metal which is stable in the air at ordinary temperatures.

Zinc unites with oxygen to form one compound, namely, zinc oxide (ZnO), which is itself infusible and unaffected at ordinary temperatures, but is volatile at a white heat. Zinc oxide is reduced to metal by carbon and carbon monoxide at a bright red heat; thus,

When zinc oxide is heated with carbon (coal or coke) to its reducing point, zinc is first reduced by the carbon. The carbon monoxide formed itself reduces oxide of zinc and is converted into carbonic acid CO_2 . Zinc is oxidized by carbonic acid giving rise to zinc oxide and carbon monoxide. So long as there is an excess of red-hot carbon present the carbonic acid has no oxidizing effect upon the reduced zinc as it is immediately reduced by the carbon to carbon monoxide; hence, in the distillation process an excess of carbon is added, so that some undecomposed carbon remains after its completion. These reactions are of the greatest importance as nearly all of the spelter of commerce is produced by processes which depend upon the above chemical facts.

At a red heat, hydrogen reduces zinc oxide, but the resulting water vapor again oxidizes more or less of the zinc.

Both zinc and zinc oxide, when heated together with sulphur, are attacked, zinc sulphide being produced. Zinc can be completely converted into a sulphide by fusion with alkaline sulphides.

At high temperatures zinc oxide unites with silica to form silicates and with alumina to form aluminates. The present large loss of retorts is mainly due to this. Zinc oxide melts with fixed alkaline carbonates to fluid, colorless slags when the proportion of carbonates to zinc oxide is five or more to one.

Zinc oxide is dissolved by an aqueous solution of ferric chloride; thus,

When finely divided zinc sulphide is subjected to a red heat in the air, zinc oxide, zinc sulphate, and sulphur dioxide are formed. When the temperature rises to a cherry red, the zinc sulphate is decomposed into sulphur trioxide, sulphur dioxide, oxygen, and basic zinc sulphate; as the temperature approaches a white heat the basic zinc sulphate is decomposed, giving rise to zinc oxide, sulphur trioxide, sulphur dioxide, and oxygen. These reactions are of importance, as upon them depends the successful roasting of sulphide ores (zincblende).

Zinc sulphide when heated with carbon and lime gives rise to zinc and calcium sulphide; the reaction is, however, incomplete. At a bright red heat iron decomposes zinc sulphide.

Zinc silicate strongly heated with carbon and lime is almost completely reduced.

Zinc carbonate is reduced to metallic zinc when heated to the reduction point of zinc oxide, together with carbon or carbon monoxide.

Zinc sulphate when slowly heated to redness with carbon is converted into zinc oxide; at a higher temperature the zinc oxide is reduced to metal. If the zinc sulphate is heated rapidly to whiteness in the presence of carbon, zinc sulphide and carbon monoxide are formed. Zinc sulphate or chloride in solution are decomposed by the electric current, zinc going to the cathode and the acid radical to the anode.

Zinc forms alloys with many metals. Some of these alloys, notably those of zinc and copper, and zinc and tin, are of considerable commercial importance. Zinc forms alloys with silver and gold, and has a greater affinity for the precious metals than lead has. Upon this fact an important process (Parks) for the extraction of gold and silver from base bullion (lead-bullion) is based.

ZINC ORES.

Zinc ores generally occur associated with lead ores and frequently with pyrites and marcasite. Thus the blendes of the Upper Mississippi Valley, of Missouri, and Kansas are generally associated with galena, whilst the blendes of the Rocky Mountain States are generally complex ores carrying galena, iron and copper pyrites, and frequently gold and silver. There are a few exceptional deposits in the United States where the ores are free from lead. The vast zinc deposits of Franklin Furnace and Ogdensburg, N. J., are of this character, and carry minerals (franklinite, willemite, and zincite) which are elsewhere considered as rarities. The zinc ores of Friedensville, Pa., consist of blende and its oxidation products, calamine and smithsonite, and are entirely free from lead, although a little pyrite occurs with the blende. At Hanover, New Mexico, there are deposits of smithsonite, calamine, and blende free from lead; but the blende frequently carries pyrites and the oxidized minerals are sometimes stained with manganese.

Blende is by far the most important ore of zinc, as it is the most abundant. It is found in all parts of the world, and in most geological formations. The other zinc minerals are sometimes of local importance as ores.

Zincblende or Sphalerite (ZnS).—Color: wax-yellow, brownish-yellow, to black, sometimes green, red and white. Streak: white to reddish brown. Luster: resinous or waxy, sometimes sub-metallic. The mineral is brittle and has a hardness of from 3.5 to 4 and a specific gravity of from 3.9 to 4.2. Its composition (when pure) is zinc 67 per cent. and sulphur 33 per cent.; but the black variety (marmatite), common to the Western States, contains iron sulphide. The ore is usually associated with other sulphides, as pyrite, marcasite, galena, etc., and gangue minerals, as quartz, calcite, barite, etc.

Zinc Silicate or Calamine ($Zn_2SiO_4 + H_2O$).—Color: white to whitish, sometimes bluish, greenish, or brownish. Streak: uncolored. Luster: vitreous or subpearly. The mineral is transparent to translucent, is brittle, has a hardness of 4.5 to 5, and a specific gravity of 3.16 to 3.9. Its composition (when pure) is zinc oxide 67.5 (zinc 53.7) per cent., silica 25 per cent., and water 7.5 per cent. It is generally found associated with other oxidized zinc minerals, especially smithsonite, and gangue minerals. It is an important ore of zinc at Altenberg, Germany; in Sardinia; in Spain; and occurs in numerous localities in the United States associated with the oxidized zinc minerals and also with blende.

Willemite (Zn_2SiO_4).—Color: whitish, greenish yellow, apple-green, flesh-red, yellowish brown. Streak: uncolored. The mineral is brittle, transparent to opaque, has a hardness of 5.5, and a specific gravity of from 3.89 to 4.18. Its composition (when pure) is zinc oxide 72.9 (zinc 58) per cent., and silica 27.1 per cent. It is an important ore of zinc at Altenberg, Germany, and in New Jersey.

Franklinite [$3(FeZn)O + (FeMn)_2O_3$].—Color: iron-black. Streak: dark reddish-brown. It is a brittle mineral having a hardness of from 5.5 to 6.5 and a specific gravity of from 4.85 to 5.1. It is attracted by the magnet. Its composition varies somewhat but the pure mineral contains from 11 to 21 per cent. of zinc. It is an important ore of zinc and manganese at Franklin Furnace, N. J.

Red Oxide of Zinc or Zincite (ZnO).—Color: deep or bright red. Streak: orange-yellow. Luster: brilliant, subadamantine. Translucent or subtranslucent. Its hardness is from 4 to 4.5 and its specific gravity from 5.4 to 5.7. Its composition (when pure) is zinc 80.3 per cent. and oxygen 19.7 per cent. It is quite abundant in New Jersey and occurs sparingly as an oxidized product in the upper portions of many zinc deposits.

Zinc Carbonate or Smithsonite ($ZnCO_3$).—Color: impure white, sometimes green or brown. Streak: uncolored. Luster: vitreous or pearly. Subtransparent to translucent. It is brittle and has a hardness of 5 and a specific gravity of from 4.3 to 4.45. Its composition (when pure), is zinc oxide 64.8 (zinc 52), and carbon dioxide 35.2 per cent.; but it is usually found associated with the carbonates of cadmium, iron, manganese, lime, and magnesia, and with clay and iron oxide. It occurs in the upper decomposed or oxidized portion of many veins and was formerly an important ore of zinc.

GEOGRAPHICAL DISTRIBUTION OF THE ORES OF ZINC.

Zinc ores are found in many parts of the world; but localities where ores occur sufficiently pure and rich in zinc to permit of the economical extraction of the metal, under existing conditions, are limited.

In Europe, the chief localities are: Germany (the Harz, the Erzgebirge, Silesia, Upper Silesia, Rhine districts, Westphalia, and Baden), Austro-Hungary (Bohemia, Carinthia, Hungary, and Tyrol), Italy (Sardinia, Lombardy, and Piedmont), Belgium (Corphalie and Engis), Russia (Poland, Allagin, and the Donetz Basin), Spain (Satander, Grenada, Carthage, Almeria, and Castillon), Greece, England (Wales, Cornwall, Cumberland, Isle of Man, Anglesea, Denbighshire, and Shropshire).

In Africa (Algeria), Australia (New South Wales), Tasmania, Siberia (Altai), South America (Huanchaca), Mexico, Canada, and British Columbia extensive deposits of zinc ore have been discovered.

In the United States, zinc ores are very widely distributed, but zinc mining is carried on at comparatively few places.

In the eastern section the mines adjacent to Franklin Furnace, N. J., the mines of the Saucon Valley, Pa., and the mines of Wythe County, Virginia, are the only localities of commercial importance at present. (For a description of these deposits see *The Ore Deposits of the United States*, by J. F. Kemp.)

The Upper Mississippi Valley region produces considerable zinc, the principal deposits being found in Southwest Wisconsin, Eastern Iowa, and Northwestern Illinois. These ores are associated with galena and frequently with a little pyrites. (For a description of these deposits see a paper by Dr. W. P. Jenney, in *Transactions American Institute of Mining Engineers*, Volume XXII.)

The bulk of the spelter product of the United States is at present derived from the ores of Southwest Missouri and Eastern

Kansas. The ores are zincblende and subordinate galena with their oxidized products, associated with chert, residual clay, calcite, and small quantities of pyrite. (For a description of these deposits see the reports of the Geological Survey of Missouri.) A small quantity of zinc ore is also produced in Central Missouri, Kentucky, and Tennessee.

Numerous deposits of complex sulphide ores, carrying more or less zincblende, occur in the Rocky Mountain region (Colorado, Utah, Montana, New Mexico, and Arizona). On the Pacific slope complex sulphides carrying zincblende have been opened in Nevada, California, Oregon, and Washington. Although small shipments of zinc concentrates have been made from some of these deposits, and whilst considerable zinc-lead pigment is produced at Cañon City, Colorado, from complex ores, up to the present time the production of zinc from these sources has been insignificant. The blende is almost invariably associated with galena and pyrites, and the ores usually carry considerable gold and silver intimately associated with the various sulphide and gangue minerals.

THE EXTRACTION OF ZINC FROM ITS ORES.

The following are the various methods which are in operation or have been proposed for the extraction of zinc from its ores. In addition to the methods described a number of schemes have been proposed and patented, but so far they have not been adopted on a commercial scale. So far as the commercial production of spelter at present is concerned the dry process is the only one of importance, nearly all of the metal of commerce being produced in this way.

1. *Dry Processes.*—Belgian, Silesian, and Belgo-Silesian methods.
2. *Wet Processes.*—Generally a combination of a wet or chemical process and the dry distillation process.
3. *Electro-metallurgical Processes.*
4. *Processes in which the zinc is obtained in the form of oxide or pigment.*

As metallic zinc cannot be separated from its solutions by any of the metals which are stable at ordinary temperatures the wet methods resolve themselves into a combination of a wet process in which the metal is generally obtained in the form of oxide, which has to be reduced by a dry process, or in a solution from which the metal is precipitated electrolytically.

Preliminary Operations.—Before the ore is subjected to the extraction process it generally has to undergo a preliminary treatment. This preliminary treatment may comprise one or more operations, according to the object to be attained.

The ore may be associated with, or contaminated with, particles of gangue, which have to be removed by dressing or concentrating operations. The ore may be a complex sulphide having quartz, pyrites, and galena associated with the blende. Such an ore would require at least the partial removal of the galena and pyrites before it could be profitably subjected to the dry extraction processes in vogue at present. At Franklin, New Jersey, the ore consists of franklinite, willemite, and zincite in a gangue which is principally calcite. The franklinite is valuable for its zinc and manganese contents when it is separated from its associated minerals. The willemite and zincite together constitute a valuable ore of zinc when separated from the franklinite and gangue, largely on account of the remarkably pure spelter which their reduction produces. This complex problem has been solved in a unique and most satisfactory manner by the introduction of the Wetherill magnetic concentrating machines* which separate the franklinite from the other minerals. The willemite and zincite are subsequently separated from the gangue on ordinary jigs. Carbonate ores carrying calamine must be subjected to a preliminary calcination to drive off the combined water and carbonic acid before they are subjected to the distillation process. They also frequently contain clay, iron oxide, and silica, which have to be removed by dressing before the material is subjected to the distillation process; it not being, so far, profitable in the United States to treat material carrying much less than 55 per cent. of zinc. Sulphide ores must be subjected to a preliminary calcination or roasting to drive off most of the sulphur and to convert the zinc into an oxide, or a mixture of oxide and sulphate. Before the ores can be subjected to the dressing or roasting operations they must undergo a preliminary crushing and pulverizing. Want of space forbids a discussion of these preliminary operations in the present article, and the reader is referred to the writer's previous articles on crushing, concentration, and roasting. (See *MINES AND MINERALS* for November and December, 1896; January, April, May, June, July, and August, 1897; and April, May, and June, 1898.)

DRY PROCESSES OF EXTRACTION.

The methods which have been adopted up to the present time depend upon the property of carbon and carbon monoxide

* *Transactions American Institute Mining Engineers*, Volume XXVI, page 351; also *The Mineral Industry*, Volume VI, page 677.

to separate metallic zinc from oxides and silicates of zinc at a high temperature. The oxidized ores in which the zinc is present as oxide or silicate are suited to direct reduction. Carbonate ores require preliminary calcination, and sulphide ores require a preliminary oxidizing roasting to convert the zinc into oxide. The reduction of zinc begins below the boiling point of zinc (a moderate red heat), but is only complete at a temperature approaching a white heat. Hence, the temperature must be increased to a point above the boiling point of zinc, the metal being separated in the gaseous state and being subsequently condensed to liquid metal. As zinc vapor is oxidized by air, water vapor, and carbonic acid, the gaseous zinc must not come into contact with these gases. The zinc vapor is only condensed between definite limits of temperature (415°C. and 550°C.). If the temperature falls below 415°C. the metal is condensed in the form of zinc fume or blue-powder, and if the temperature rises above 550°C. the metal remains in the gaseous state. This necessitates great care in the selection of the carbonaceous material to be mixed with the ore as a reducing agent, for should it contain too large a proportion of readily volatile matter the gases will drive out the zinc vapor too rapidly to allow of its complete condensation, thus making a great difference in the percentage of extraction. These facts render the extraction of zinc one of the most difficult and imperfect of modern metallurgical operations. The high temperature required for the reduction necessitates the use of first-class and expensive refractory materials for the reduction apparatus. This reduction apparatus consists of closed fireclay vessels

FIG. 1. CROSS-SECTION BELGIAN FURNACE.

which generally have the form of tubes or muffles. The capacity of these vessels is not great, and as they are liable to rapid destruction their cost is high. There is always a considerable loss of metal in the distillation process (from 10 to 30 per cent. of the zinc contents of the ore) as the material of the retorts always retains some zinc combined as aluminate, and some zinc invariably remains in the residues; but principally owing to imperfect condensation of the zinc vapors. Additional losses are caused by defective retorts and condensers.

The various dry processes which have been used on a commercial scale up to the present time are as follows:

English Process or Distillation per Descensum.—This method was introduced at Bristol, England, by John Champion in the year 1740. The oxidized zinc ore was mixed with carbon and heated in large fireclay crucibles. The

crucibles were 4 feet high and $2\frac{1}{2}$ feet wide on top, having an opening in the bottom to which a sheet-iron pipe, 6 inches in diameter and passing through the bottom of the furnace into the vault below, was attached. The lids of the crucibles were cemented on so as to make a tight joint. The zinc vapor, as it was liberated from the ore, descended and was condensed in the iron tube. The method was wasteful and expensive and has been entirely abandoned.

Carinthian Process.—This was similar to the English method except that fireclay tubes were employed instead of crucibles; the lower part of the tubes projected through the furnace bottom and the vaporized zinc condensed here. The process has been entirely abandoned.

Belgian Process.—This method, which was introduced in 1810, has grown in favor until the greater portion of the spelter of commerce is produced by this process. It is the only process in commercial operation in the United States at the present time for the production of spelter.

One of the older forms of Belgian furnace is shown in the illustrations (Figs. 1 and 2), which present a cross-section through the retorts, and a front elevation showing a few of the retorts in place. Fig. 3 is a side view of a single retort in position. The flames generated by the combustion of the coal on the grate *a* travel up and around the retorts *c*, ascending in the shaft of the furnace, and escape through the ports *s* out of the furnace and into the stack *m*. To the retorts *c* are attached the conical fireclay adapters *x* in which the zinc vapors are condensed. To the adapters are attached the sheet-iron nozzles *y* in which the zinc fume is caught. The common practice in the United States is to

substitute for these nozzles simply a handful of the next ore charge, slightly moistened, through which all vapors must percolate before escaping into the outer air. This is more simple and is said to be more efficient than the use of nozzles. The retorts are supported at the rear end by the firebrick projections *b*, Fig. 3, and at the front end by the fireclay slabs *e* of the front wall of the furnace. The cast-iron plates *l* form the continuation

FIG. 2. FRONT ELEVATION BELGIAN FURNACE.

of these slabs, and the firebricks which serve to support the adapters *x*. The retorts are arranged in from six or seven rows above each other, so that most of their outside surface will be surrounded by the flames. The furnaces are either single furnaces with one shaft, or double furnaces built back to back, with two shafts separated by a vertical

partition wall. The number of retorts per furnace varies from 50 to over 400 (the larger number being only practicable in gas-fired furnaces), according to the dimensions of the furnace. According to the method of firing which is adopted, the furnaces may be classified as follows: Furnaces fired by grates, furnaces fired by grates and gas, furnaces fired by gas. The gas-fired furnaces, which are heated by producer gas, have been largely adopted of late years, especially in the United States. They present the advantages, as compared with direct-fired furnaces, of being independent of the nature of the fuel, and, consequently, being adapted to very inferior coals, of consuming less fuel, of consuming fewer retorts, and of extracting a higher percentage of zinc. The gas-fired furnaces may or may not be provided with regenerators. Although regenerator furnaces consume less fuel and attain higher temperatures, they are not largely employed in the Belgian process on account of the regenerator flues becoming choked with zinc oxide, on account of the difficulty of keeping the heat uniform in the high Belgian furnace which results in the retorts becoming overheated, and also on account of their high first cost. With the low and broad Silesian muffle furnace, gas-fired regenerator furnaces have proven satisfactory and economical. In the United States, furnaces fired by natural gas have been extensively adopted in the past few years. At Iola, Kansas, furnaces fired by natural gas have 350 retorts on a side or 700 retorts to each furnace, there being a central partition wall which divides the furnace and extends to the flat reverberatory arch on top. There is one stack at the end of each furnace to carry off the products of combustion. The iron gas mains and the blast pipes which convey the air under pressure for the combustion of the gas, pass over the arch of the furnace. By this arrangement both the gas and air are preheated before their introduction into the furnace. The retorts are arranged in six tiers and there are four gas jets between each double vertical row of retorts. At this works Ropp straight-line furnaces are employed to roast the ores prior to their distillation. The roasting furnaces are also fired by natural gas. Furnaces fired by natural gas present all of the advantages of furnaces fired by producer gas, with the additional advantage of a very cheap fuel. In fact, at Iola, natural gas is furnished to the zinc smelters free of charge.

The retorts used in the Belgian furnace are either cylindrical or elliptical tubes. The material of which the retorts and the receivers or adapters are composed is a mixture of fireclay and burnt clay, or burnt clay and quartz, or a mixture of fireclay and pulverized pieces of old retorts. Sometimes fine coke is mixed with the fireclay.

The proportions of the various materials vary according to their quality and also according to the nature of the ores to be treated in the vessels. The retorts vary in size, the walls being from $\frac{3}{4}$ inch to $1\frac{1}{2}$ inches in thickness, the internal diameter is from $7\frac{1}{2}$ to $8\frac{1}{2}$ inches, and the length varies from 3 feet 3 inches to 4 feet 9 inches. When the cross-section is elliptical the long axis

FIG. 3.

is 8½ inches to 12 inches, and the short axis is 6½ to 8 inches in the clear. Larger retorts, which are rectangular in cross-section and have the following dimensions: length, 5 feet; height, 20 inches; width, 9 inches; have been employed. The length of the retorts is limited on account of their being supported at their extremities, and, hence they must carry their own weight and also the weight of the charge without bending or breaking. The retorts were formerly made by hand, but in most modern plants they are now made by machines, which are operated by hydraulic pressure. These machines are similar to those used in the manufacture of sewer pipe. The materials for the retorts are first crushed by means of edge runners or disintegrators, and are then kneaded to a uniform mass with the addition of about 8 per cent. of water. The raw clay, which constitutes about 50 per cent. of the mixture, is ground to a fine flour, whilst the burnt clay and the fragments of old vessels is ground to pass a 4- or 5-mesh screen. The kneading is accomplished in a pug mill, and after the mass is thoroughly kneaded it is stored for from six to eight weeks, to render it more plastic. After moulding, the vessels are air dried for about three weeks and are then dried in heated chambers for two or three months. The temperature of the drying chambers is at first 25° C. and it is gradually increased to 70° C. After drying, the vessels are heated in kilns, the temperature being brought up to a red heat during the last 12 hours. In starting up a new furnace the dried retorts are put in place and burned in the furnace itself. With an old furnace the retorts are heated in the kilns to a red heat and introduced into the furnace in that condition.

Before a furnace is put into operation it is fired gently for some days with empty retorts in place. When it has become thoroughly dried and heated the retorts are charged and the heat is increased gradually. The charges are prepared for reduction by mixing or grinding the ores with coal, no fluxes being added. When a variety of ores are obtainable they should be mixed so as to produce a purely siliceous or a purely basic charge; bases such as iron and lead which form fusible compounds being excluded. If this is impossible they should be so mixed that the bases and the silica will form a slag as infusible as possible at the reduction temperature of the zinc. The reducing agent is lean (non-gaseous) coal, small coke, or a mixture of the two. The amount of reducing agent varies somewhat according to the nature of the ores. For calcined smithsonite and calamine it amounts to from one-third to half the weight of ore, according to the zinc contents. For calcined blende it amounts to from 40 to 50 per cent. of the weight of calcined ore. The blende should be pulverized to pass at least a 14-mesh screen. The calcined oxidized ores being more readily reduced need not be so finely pulverized. The mixing of the ore and the reducing agent is accomplished by hand or, in large works, by separate crushing of the ingredients of the charge and then mixing mechanically. The charges are introduced into the retorts, after removal of the adapters, by means of a semicylindrical scoop attached to the end of an iron rod. The first charges are light, the weight of charge being gradually increased, until, at the end of about five days, normal charges and conditions are attained. These retorts, which are subjected to the highest temperature, receive the heaviest charges. The retorts which are subjected to the lower temperatures are charged with substances which are readily reduced as zinc fume, and zinc-bearing residues, and with ores which sinter readily. The average charge for a retort is about 63 pounds of ore. After the retorts are charged the adapters are attached, the joint being luted with a mixture of loam and coal dust. Some little time after charging, a flame of burning gases escapes from the adapters, and this flame in time changes to the brilliant flame of burning zinc vapor. The nozzles, when used, are now attached to the adapters in order to avoid loss of zinc. Although the adapters soon attain the necessary temperature no fluid zinc condenses in them at first, in consequence of the carbonic acid and water vapor present in the first gases which convert the zinc into oxide. Zinc fume is also largely produced at this stage on account of the greatly diluted condition of the vapors. It is only after the water vapor and carbonic acid cease to be given off that the zinc vapors condense to liquid zinc. The temperature of the furnace must be closely watched, for if too high a temperature is attained, large quantities of zinc fume will be produced, owing to the imperfect condensation of the vapors in the adapters. The condensed zinc is generally removed from the adapters several times during the operation or, occasionally, only once after its completion. In the latter case the nozzles are removed and the zinc is drawn out of the adapters with a scraper. It is drawn into ladles, its surface is skimmed, and it is cast into slabs weighing from 40 to 45 pounds each. The time required for distillation varies from 12 to 24 hours and depends upon the size of the retorts and the furnaces, upon the location of the retorts in the furnace, upon the reducibility of the charge and largely upon the quality of the fuel used. When distillation is finished the adapters are removed and the retort residues are drawn out with scrapers which remove the bulk of the material, the balance being

blown out with a steam jet which serves to clean the retort more effectually than is possible with scrapers.

The total charge of a furnace depends upon the number of retorts which it contains, and varies from 1,000 pounds to several tons of ore. The consumption of fuel depends upon the method of firing adopted and the quality of the coal, varying from 1½ to 2½ tons per ton of ore treated. The life of the retorts depends largely upon the quality of the materials used and their method of manufacture; retorts made of good material and by hydraulic pressure, have an average life of about 40 days. With a modern furnace the loss of zinc seldom exceeds 10 to 12 per cent. With furnaces provided with retorts holding on an average 63 pounds of ore, one man is required for 28 retorts for each shift of 12 hours. The consumption of fireclay, including that used for retorts, adapters, and firebrick is about 400 pounds per ton of zinc product.

(To be Continued.)

The Reduction of Freight Rates.

It is well known that a large part of the price of iron and coal, as delivered to the consumer, represents cost of freight from the mines to the markets, and cost of handling the material; therefore a reduction of this cost has seemed to be a promising point of attack for reducing prices. A recent article in regard to how this reduction may be effected, written by J. T. Odell, vice-president of the Pittsburgh, Bessemer & Lake Erie Railroad, for the *New York Evening Post* says:

It is within the memory of the older railway managers when the capacity of the freight cars was 8 tons, the weight of the rail 50 pounds to the yard, the weight of locomotives 36 tons, the capacity of the bridges 2,000 pounds rolling weight to the lineal foot, and the speed of passenger trains about 30 miles per hour. Within the short period of 35 years the capacity of the cars has been quadrupled, the weight of the rail nearly doubled, the locomotives increased in weight two and one-half times, the carrying ability of the bridges increased two-fold. These striking improvements of the permanent way, motive power and rolling stock have borne great fruit in rendering possible the reduction in the last 16 years of the freight rates from 33 to 50 per cent. These accomplished results render it, therefore, reasonable to suppose that the time is coming when such low ocean rates will become permanently practicable, as will insure a constant export of our surplus products with a fair remuneration to shippers and carriers.

Railway managers are greatly agitated over the question of "ton-mile cost," which means, of course, the question of the relative spread between dead weight and paying load of the freight trains. Probably 55 per cent. of all the weight hauled by the locomotives of the freight trains is dead weight, and only 45 per cent. paying load. This spread makes too great a "ton-mile cost." It is out of proportion to the freight rate, and the percentages must be reversed. This is what all the roads are striving to attain, but it means heavy expenditure for a great many of them. The average paying load of all the freight trains of the country is probably less than 200 tons, which means, of course, a greater "ton-mile cost" than the probable coming export rate will stand. This partially explains the rehabilitation of railroads now going on.

Few people outside of the immediate vicinity of Pittsburgh have the slightest conception of the enormity of the railroad tonnage drawn to and from that center, and an investigation of its traffic affords a fine field for the transportation student and will broaden him. The tonnage of the Carnegie Steel Co., alone, raw material and finished product (being 16,000,000 tons last year) is as great as the combined tonnage of the Northern Pacific, Union Pacific, and Missouri Pacific Railways, embracing as they do more than 18,000 miles of track, and running probably 1,500 locomotives and 50,000 freight cars. A few years ago the steel company became satisfied, after careful investigation, that, if a portion of their tonnage was separated from the general freight of the railroads, concentrated on a road controlled by their own company and handled in solid trains, the cost of transportation could be materially reduced and the reduced rate be remunerative to the railway. With this object in view, they secured a road of their own, running from their mills to their own docks at Conneaut on Lake Erie, a distance of 153 miles. The result of the operation of this railway shows as follows:

The lowest rate per ton per mile, the highest average length of revenue haul in proportion to its track mileage, the greatest density of tonnage in proportion to its freight-train mileage, the greatest average paying load, and the lowest "ton-mile cost" of any road on the American continent reporting to the Interstate-Commerce Commission. The average paying load of all its freight trains, including three branches, and with but little back-loading, was, for the year ending December 31, 1899, 777 tons. It is confidently expected when the south and north-bound tonnage is 70 per cent. and 30 per cent., respectively, and the tonnage reaches 5,000,000 tons annually, as it promises, that the average paying load will be not less than 900 tons, or four and one-half times greater than the present average paying load of the country. The maximum weight of the paying load for the year was 1,580 net tons, with the average as before stated of 777 tons. Of the ore trains, each earned on a 3½-mill rate per ton per mile (gross ton) \$5.13 per train mile. The road is laid with 100-pound rail and the track ballasted with furnace slag. The bridges will carry 6,600 pounds to the lineal foot. The standard locomotive is the consolidation pattern, having cylinders 22 in. × 28 in. and weighing 170,000 pounds on the drivers alone. The ore equipment consists mostly of steel cars, weighing 17 tons and carrying 50 tons of ore. The company is having built a few of what will prove to be the heaviest locomotives in the world, having cylinders 23 in. × 32 in., and weighing 217,000 pounds on the drivers. With these locomotives the total weight of an ore train, including the locomotive and light weight of the cars, will be about 2,600 tons.

But it is not only in the operation of the road that greatest economy is obtained, but also in the transfer of the ore from the lake steamers to the trains. The steel company owns the entire harbor at Conneaut. Nine ships can be docked at the same time. Twenty-five thousand tons of all classes of freight can be handled every 10 hours. The most modern machinery is used for handling ore and coal. A 6,000-ton ship can be cleared in 14 hours, and in the same time from the moment the hatches are opened the ore can be at the furnaces at Pittsburgh. A new steam shovel was completed last winter by which a train of 35 to 40 cars will be loaded with ore in 2 hours. A 40-ton car of coal can be unloaded and partly trimmed in the ship in 36 seconds. Most of the switching at Conneaut is done by the haulage system (a cable running between the rails at about 4 miles per hour). The operating officers believe that with this railroad the utmost limit of all that is possible in solving the problem of cheap transportation has been reached. Their achievement shows what remains to be done, and can be done by the other railroads of this country in the same direction.

Rock Determination.

The Western Editor of MINES AND MINERALS will, without charge, examine and name, so far as possible, samples of rock sent him, the answers being sent by postal card to the sender of the specimen. He will only undertake to name average rocks, such as can be fairly determined at sight; and microscopic or chemical analyses will not be attempted; neither is it always possible to determine with absolute precision and certainty a small sample, or one decomposed and oxidized, and with such samples the sender must be content with the provisional determination that it *appears* like such and such a rock.

Questions involving an opinion on mining property, for which an expert would be entitled to a fee, will not be answered, but advice that will aid the prospector will be given.

The following conditions must be observed by those sending specimens for determination:

The specimens should be fresh and about 2 inches square.

Each should be distinctly labeled.

The name and address of the sender, written very distinctly, must be enclosed in the package.

The package should be sent prepaid to Prof. Arthur Lakes, Room 608 Boston Building, Denver, Col.

A letter should accompany the specimens describing the locality, mode of occurrence of the rock and other facts, and rough sketches may accompany such descriptions.

Samples will not be returned unless by request, and where stamps are enclosed to cover postage or expressage and cost of packing.

The Granitic Rocks.

Granite is such a familiar rock that we might think that every one would know it when they saw it and not be likely to mistake it for other rocks. But such is not quite the case. We have met prospectors and miners who mistook granite for other varieties of eruptive rock, and vice versa. One man, for instance, told us he "had granite for the roof of his tunnel and limestone for the floor;" in other words, the impossible condition of granite overlying limestone. On examination we found the so-called granite to be a peculiar granite-like intrusive porphyry sheet.

The great Elk Mt. diorite laccolites were for a long period said to be "eruptive granite," and no wonder, for the rock diorite is often at sight scarcely distinguishable from some granite; and so with many of the eruptives, miners either calling them granites, or trachytes, both terms being commonly incorrect.

As a rule, in Colorado at least, we may say that when bodies of igneous, crystalline rock are found overlying, or intruded up through sedimentary rocks, cutting across the beds or sending out sheets between the sedimentary strata, or overlying the strata, these are never granites, but some other form of eruptive rock. In Colorado, the granite *underlies* all sedimentary rocks, though by its erosion it may tower above them.

That granite should be confused with other eruptive rocks from its similarity in appearance to them is the more pardonable when we find how closely related granite is to many of these, both in structure, texture, and origin, and how many of these igneous rocks bearing different names may have been indirectly derived from the parent granite, by a natural passage or transition, in some cases perhaps by a local chill, in others by an excess of heat, or other fortuitous circumstances. In fact it would seem as if granite might be indeed the parent of almost all rocks, not merely the fragmental sedimentaries whose origin from it is obvious, but even the so-called igneous and volcanic rocks to which we give various names. There is none of these latter rocks but what carries in it some of the same elementary minerals as compose granite, and others which by transmutation might be referred back to them.

Composition.—Granite proper is made up of three principal minerals, viz., quartz, mica, and feldspar; when hornblende is added with the mica it is called hornblende granite. Granite with black mica, or biotite, in it is commoner than with white mica or muscovite. When biotite is alone present the rock is sometimes by ultrarefinement called "granitite." Large crystals of both micas very often occur in dikes or veins of coarse sparry granite, commonly known as pegmatitic veins.

The quartz in a piece of granite is generally easily distinguishable by its gray, crushed, transparent, broken glass-like appearance, showing no crystalline face or form. On the other hand, the feldspars are recognizable by their generally showing a portion of one flat face of their crystals glistening in the sun. Moreover, the feldspars are generally opaque, and commonly pink, red, or opaque gray or white. In a few cases they are white and transparent but even then can be distinguished from quartz by showing cleavage or crystalline faces. In the Front range of Colorado the feldspars are mostly a pale flesh color, producing a reddish granite; higher up in the range, the feldspars are often white and give a whitish or gray granite. The micas are easily recognized by their bright glitter and color; hornblende, when present, by its duller luster than mica, its greenish black tint, and its longer crystals.

Granite, as distinct from many of the porphyries and igneous lavas, has all its crystals crushed together in a general crystalline mass like lump sugar. You cannot extract from the rock any one

perfect crystal like a plum from a pudding, as you can out of some porphyries. There are occasions, however, where granite assumes a porphyritic habit with distinct feldspar crystals in a crystalline, finer-grained ground mass, as for instance, that forming the summit of Pikes Peak; such porphyritic granite is on its way to passing into a true porphyry.

The chemical analysis of a typical black mica granite as given by Kemp is: SiO_2 , 73.76; Al_2O_3 , 13.43; Fe_2O_3 , 1.16; CaO , 1.41; MgO , 0.75; K_2O , 5.22; Na_2O , 4.01; loss, 0.42; specific gravity, 2.63.

As silica decreases the bases increase. Soda tends to exceed potash, making the passage to diorites. Granites are made up of orthoclase feldspar with sometimes microcline and acid plagioclase feldspars, quartz, and micas; besides these, magnetite, apatite, zircon, and garnet are often present; these latter are generally very small or microscopic crystals.

When no dark silicates occur, but only quartz and feldspar, the rock is a "binary granite," or may be called a "pegmatitic granite," such for example, as the fine-grained deep red eruptive granite of part of Cripple Creek, composed of deep red orthoclase feldspar, and some quartz with little or no mica or hornblende. "Aplite" or pegmatitic veins is the name commonly given to the so-called miners' "quartz veins" in granite, which are generally an aggregate of rather large sparry crystals of feldspar and quartz with little or no mica.

Such veins are common in our cañons and form the matrix of many of our gold and silver ores. These veins might sometimes, in a sense, be called "dikes." Portions of these pegmatitic veins may be of that peculiar rock known as "graphic granite," formed of long blade-like intergrowths of crystals of quartz and feldspar, which when cut by a cross-fracture, suggest Hebraic characters. Garnet, tourmaline, beryl, epidote, and various other gem-like crystals are found in these veins of pegmatite. These veins, or dikes, may be 100 feet wide, or only tiny little lenses or ribbon-like wrinkles. Kemp considers that these larger veins or dikes could hardly have been produced by true igneous fusion to create such coarsely crystalline aggregates. "So we are forced to assume," he says, "such abundance of steam and other vapors, as to almost, if not quite, imply solution."

Just as porphyritic granites may pass into true porphyries, so the distinct crystals of granite porphyries may fail, and the ground masses becomes finer and finer, passing through a stage called microgranite into the felsites. The outer portions of granite masses are often subjected to the action of escaping vapors containing boracic and hydrofluoric acid (fumarole action); these develop into tourmaline, fluorite, and sometimes tin.

The colors of granite depend upon that of its constituent minerals, and the abundance or not of one kind of mineral. Thus, red granites are due to their red feldspar; white granites to a preponderance of white feldspars, and gray or dark gray granites to an abundance of mica or hornblende. Granites pass through granite porphyries and microgranites into quartz porphyries and felsites; along the borders of an intrusion this change can be traced inch by inch to a place where the porphyritic texture is due to a quick chill; granitoid rhyolites, or nevadites are closely related to granite.

As quartz decreases syenites or quartzless granites may result by insensible gradation, and as hornblende or biotite and plagioclase feldspar increase the same passage is to diorites. Intermediate varieties are granite diorites. Granite, also, by increase of augite and plagioclase passes into "gabbro." So we see how closely related granite is to other granite-like rocks called by very different names. Granites in great irregular masses that have solidified at depths and before consolidating have fused their way upward by melting into themselves overlying rock are called "bathylites." Granites appear as irregular rounded outcrops in the midst of other rocks, as bosses, knobs, and dikes. There is no reason why granites should not form at all geological ages, but those open to our observation are mostly of Archean and Paleozoic age, because being deep-seated rocks, only the older ones have been exposed by erosion.

Granites break apart by jointing planes in rectangular blocks and often look like portions of Cyclopean walls of masonry.

These are sometimes eroded away until only a single tower is left standing on the granite plain. Of such are the Cheese Rings in Cornwall comparable to a pile of cheeses lain one on top of the other. These were doubtless used by the Druids for sacrificial altars, the blood of the sacrifices being, at times, poured into circular holes worn out by rain erosion into natural chaldrons.

It is not uncommon in parts of the mountains to see fragments of Algonkian schists that once overlay the granite partially fused and incorporated into the granite itself. Granites are among the strongest of building stones, the crushing resistance ranging from 10,000 to 25,000 pounds per square inch in a 2-inch cube. The important points in a building-stone granite are homogeneity of texture, good rectangular cleavage in the quarry, adaptability to tool treatment, and pleasing color.

Decay of Granites.—In decay, granites suffer first by oxidation of protoxide of iron in the iron manganese silicates, biotite mica, and hornblende, and the formation of a greenish substance called chlorite. The feldspars kaolinize, or turn to china clay. In Cornwall, near St. Austel, in the hills above the town is a whitish granite containing a large proportion of white feldspar. Springs issuing from these granites have decomposed their lower portions, producing extensive beds of fine white kaolin, china, or pipe clay. This is run down into vats where the quartz and mica separate by settling, leaving a residuum of pure white clay. The streams that originate in these beds now appear to run in milk since the works were opened. Most of our kaolin, or porcelain clay used for making white chinaware is derived from the feldspars of granitic or igneous rocks.

As regards the oxidation and decay of the blacker constituents, mica or hornblende, you will often notice a dull gray "pitted" look on the face of some granites. This results from the decay or oxidation of mica. It is often difficult at sight to determine whether these tarnished greenish-gray spots are mica or hornblende, but by inserting the point of a penknife in such dark spots, scale will come off and reveal a bright sparkling mica face below. Hornblende will not so scale off and will not show so bright a face.

We used to suppose popularly that gneisses were stratified granites laid down in beds, perhaps, by heated waters like sedimentary rocks, and such some of the late Algonkian gneisses may have been, but it is certain that many of these schists and gneissic structures have been produced by mechanical strain and shearing. Granites abound in the mountains of the United States and usually constitute the core of the ranges.

MINE TIMBERING.

Various Methods of Cutting and Placing Timbers to Secure the Best Results.

By David J. Evans, Ehrmannndale, Ind.*

All subjects pertaining to mining should be interesting to us, and not the least among them is timbering. I will try to give this institute my experience in timbering a mine, and hope that some of the members, at least, will appreciate my effort in describing this branch of practical mining.

I will not say anything in this paper about putting up props, although there are many miners who cannot, or at least do not, put them up in a way that is safe and substantial, but will confine the paper to the cross-bars, the various ways of notching, fitting, and supporting them.

The best way, I believe, to put up a cross-bar is to make a hitch in, or on top of the coal for its support whenever that is practicable; provided, however, that all loose coal, or coal that is leaning out over its bottom be taken down or cut away before making said hitches. I have seen bars put up so carelessly or in such a hurry to finish the job that the hitches have been made on top of overhanging coal that was barely able to support the weight of the bar, without considering any weight that might come on the bar from the roof. In a case like this the place has been made more dangerous instead of having been made safe. Some of you, no doubt, have seen bars that have been put up thus falling with very little besides their own weight. Such bars are nothing but traps, and a mine boss should not tolerate such timbering under any circumstances whatever.

If the coal is not high enough to get the bar to the roof, or as high as necessary, put in a block of wood on the coal, under the bar, to make it high enough. It is not good policy to make

FIG. 1.

FIG. 2.

FIG. 3.

hitches in slate, for it will often crumble with the air and may let the bar down. Put a bar up right and it is there to stay, and will give you no more trouble until it decays or is broken by weight.

There are cases, however, where the bars are too short, or the coal not solid enough to risk a bar on it, and some men will put straight props under them for support. This idea of timbering is faulty, for the reason that if the bottom is soft and any extra weight comes on the bar the prop will give way in the bottom, and not only will it sink in the bottom but will also work

towards the track where the cars by passing will strike it and make the place very dangerous, especially for the drivers.

The best way to support a bar that is not resting on the coal is with the leaning leg. Here we come to another phase in timbering. Here there is a right and a wrong way of notching. In this case it is in the leg or support where the difference is. I believe everybody that knows anything about timbering, and uses notched timber, notches the bar very nearly alike.

The fault in notching the leg is that the front or face of the leg is cut too straight up (Fig. 1). Consequently it does not

FIG. 4.

FIG. 5.

FIG. 6.

FIG. 7. •

support the bar under the notch and it gives the bar a chance, with any extra weight to split. With this kind of notching of the leg, a big per centage of the strength of the bar is lost.

Here (Fig. 3) is a better way of notching. By throwing the face of the leg well back, the bar, when weight comes on it, buries itself in the face of the leg and is therefore prevented from splitting and will support all the weight that the wood in the bar is able to support, and if the weight is excessive, the bar may bend or break but will not split.

All other timbering is only the bar and leg put in different positions, combined with other bars and legs. I will here try to describe some of those combinations.

Having to deal with bad roof over switches has caused a combination in timber. Here again the bars on the coal can be put up, provided the place is suitable for them. Put one bar across the mouth of the room, the heads resting on each corner of the room, and put two more, one from each corner across the entry in very nearly a triangular shape, which, if the roof is not very bad, the bars good and strong and put up substantially, will often make the place safe.

But if the place does not suit that way of timbering and we can spare the height from the room or the place that is turning off, then we can put up a bar with both ends on the coal, or with one end on the coal and the other notched and resting on a leg; or, as I have known cases where legs have to be put under each end of a big bar and put two or more bars to rest on it with legs under them on the other side of the entry (Fig. 6). If bars are put up in this way, then care should be taken to have all the legs to lean towards one another, so that weight on one side cannot push them out of position.

Another way to timber a switch is to get two corner legs, rather large, face them on two sides—at right angles—put a bar across the room on them, also one on each of them across the entry, similar to the three bars on coal; but in this case they have to be put at right angles instead of in a triangle. The off end of the bars across the entry can be put on the coal if care is taken to wedge solid and have them of proper length so that the legs will be leaning in a little towards the main road (Fig. 5). If a bar is needed in the middle it will be its thickness above the other bars. This is a good way when you want the same height on both roads, the roof being "heavy," but not very badly broken; or where it does not require close timbering or lagging.

There is yet another way to frame a switch. The two main legs in this case also have to be rather large, the same as in the last case. Notch them on top, but at the angle that the leg leans sideways and put another notch in the side, the same as in a bar, but somewhat deeper, about the thickness of the bar, or less, below the top, then notch the bar across the room to fit in these hitches and one on each leg across the entry. I have used this kind of timbering where I had to take advantage of every inch in height. With very little work, sometimes, you may get a bar across the middle of the switch with this notch, where it would cause lots of labor with the other, or you would have to let your big bar too low (Fig. 4). If you have a place with good roof, but with side pressure, this is the best way that I know of to support it. Spread the legs as wide as possible in the bottom, let the legs lean over about 1 in 6, or may be 1 in 5 would be better, but it is not good policy to have them lean over more than that; put the bar down as low as possible without taking too much of the height, make a notch in the bar to fit the front of the leg to keep it from splitting, wedge all tight on top, and it will take a pretty good pressure to dislodge them.

You all know about timbering a double track. It is the same as timbering a single track, except that the timbers are heavier. But sometimes we have to put support in the center of these long bars. It is not desirable to have props in the center, but sometimes it cannot be avoided. When we put up bars with a center support, I think the best way is to put up good stout props in the

* Read before the Indiana Mining Institute.

center first (Fig. 2), in which two hitches have been made on opposite sides, the height you want the bars from the bottom, then wedge the post upright to the roof, facing in both tracks. Now, by cutting hitches on both sides, or by notching or putting up legs, you can get your bar up in two pieces, which will be easier handled than by putting up a big bar and then putting a post in the center. If, in this way, one part of the bar breaks, you can change it without taking the other part down at all.

There is a way, however, that the center of a bar can be supported without post if you have enough height. Put short posts in the sides, say about half the height of the bar, and set braces from them to about one-third of the bar and put a cleet in between them, and we have very near an arch of wood.

The reason that I favor the leaning leg in timbering is, that often you can set a leg on coal, which is far better than on the bottom. If putting the leg on the bottom cannot be avoided, it has a tendency to push in under the coal, which is the hardest part of the bottom, hence is more able to support the weight of the roof.

The way that is generally in use in timbering the mouths of slopes and drifts differs a little in the cut of the leg (Fig. 7). This is what I would call a double notch. The bar is notched the same in this case as other bars are, but instead of making a smooth face for the leg, a step is made in it the same distance from the top that the depth of notch is in the bar and they are fitted together. I do not think this way is any better than the other way, but others timber in this way and we want to know how. If a sill is to be put under these timbers, cut it down where you want the front of the leg and feather edge it toward the back according to the pitch of the leg and you have a good foundation. The sill ought to reach across under both legs. I think it unnecessary to mortice and tenon these timbers. These are supposed to be sawed timbers.

Timber for a timber man should come to the mine without being hewed. I like to face my own timber, for by doing so I can always put the crook in the bar up where it ought to be.

To notch timber I prefer a hatchet made by the mine blacksmith to one of those ready made from the store. It is made like a roadman's hatchet, weight about 4 pounds, with handle about 15 inches long. It is about the handiest tool I have ever used in this kind of work if made right and of good material. With this hatchet I like a good saw—seven teeth to the inch I think about right—a pair of forks made of $\frac{3}{8}$ -inch iron, a pick and shovel, and a measuring stick. I make this in two parts of two pieces of pine, 1 in. $\times$ 3 in., and tack a piece of tin or sheet iron on one end of each just the size for the other to slip through easily. It is one of the handy tools. Getting a blacksmith to put a strap of iron on one end with a thumbscrew in it would be still better. Put any marks on it to suit yourself.

The Mineral Industry in the Ural Mountains.

Of all the known mineral districts, probably none resembles our own Rocky Mountain district in the richness and variety of its resources as much as does the mineral-bearing section of the Ural Mountains. In view of the increased trade with Russia, and the fact that several American works have Russian branches, the following description of the Ural Mountains, by A. H. d'Escailles, in the *London Mining Journal*, will be of interest:

The development of the mineral and metallurgical industry in the Urals has been much discussed in Russia of late, and already a plan for the organization of an industrial bank has been drawn up, with the object of supplying credit to the mines and factories in order to facilitate the transformation of their material and the development of their explorations. The necessity of extending the railway network for the improvement of the present very unfavorable conditions of transport has also been acknowledged. Let us consider now the mineral organization. We shall, if we consult the great chart, in 12 sheets, edited by the Mines Department, showing the division of the territories in the Ural region, see indicated: (1) The domain formed by the works of the State or of "The Crown;" (2) Those of the manufactories situated on land belonging to the State, but conceded to private industrials; (3) Those of the private works; (4) The territories belong to the Cossacks and Bachkirs.

We will give a resume of the state of the industry in the most important districts of the Ural. The kinds of fuel utilized by the mineral industry are various: coal, coke, turf, wood, charcoal, and naphtha. Although Carboniferous soil exists on the western side of the mountains, and in many places coal has been found, it is only exploited in a rather limited region, and its quality is but mediocre. On the eastern side, also, coal is met with on certain spots, which were worked in olden times. Turf covers large areas, especially on the auriferous placers, where it is often utilized as fuel, and in the Verkisert district it serves to make small briquettes. Wood is extensively employed by puddlers, but

it is chiefly after carbonization, charcoal playing a preponderant role throughout the Urals. The residuum from distillation of naphtha is used in many factories, especially in the southern part of the range, and the application of naphtha to the Martin furnaces, made some time ago at the metallurgical works of Moscow, is of particular interest for the Ural region. The iron ores of the Urals are: The magnetite (in the Magnitkaia and Visokaia mountains and the Blagodat Mount); the brown hematite, met with in the south and in the middle zone, especially at Bakal; the ologishoron, which is found in the north; and the red hematite and the siderose (iron wood) which exists in the west. The exploitation of these beds is performed in a very primitive manner, which is certainly capable of vast improvement. The blast furnaces are heated by charcoal; they are generally of a medium size, and produce about 20 tons in 24 hours. The old types are still numerous, but there are, also, as at Tchussovaia, furnaces of modern construction. The blast furnaces are usually in buildings entirely closed and covered by cupolas of quite a special character. For a long time, pig iron was the sole production of the Urals, but for some few years now the fabrication of steel has steadily developed. A great number of the iron works are still carried on according to the old system, especially those that turn out thin sheet iron, which is much in demand for roofs in Russia. The puddling furnaces are also very numerous, and are generally heated by charcoal or naphtha. Steel is almost wholly manufactured by means of the Martin's furnaces and in a great number of the workshops new ones are actually in course of construction. The number of Bessemers existing in the district is only four, two of which are in one of the numerous manufactories of Nijni-Tagilek, belonging to the heirs of Demidoff, Prince of San Donato, whose ancestors founded the iron industry in the Urals. These establishments have preserved a great repute for several centuries.

The Russian production of copper was for many years restricted to the Ural region, but it has recently undergone great development in the Caucasus, for if Altai and Finland do not seriously count, the steppes of Khirghizes, if worked with modern machinery, seem capable of producing an important quantity. The copper beds of the Ural range are of two kinds. (1) Primitive beds situated on the eastern side, especially at Mednorondiansk, where the chalcopryite and magnetite are found. (2) Reworked beds on the western side, which exist in different varieties of rock, and particularly in the grit belonging to the Permian system. The ores, which are oxidized, have only a basis of 2 or 3 per cent. Mines of this nature, situated in the neighborhood of Orenbourg, towards the south of the Urals, produce also a small quantity of metal, the quality of which is much appreciated. At the present time, the two chief centers of copper production are to the northeastward of Bogosloff, where the treatment by the converter is practiced, and at Nijni-Tagilek, where oxidized and pyritic ores are treated in the following manner: Fusion of matte, roasting, reducing, fusion and affinage.

An important innovation has been practiced in the Ural region during the past few years, and which will, doubtless, add greatly to the output of metals, namely, the employment of coal. As regards gold, it is only quite recently that attention has been given to the wealth contained in the veins. The method of working is largely by piecework, and the men are called "starelli." They have transmitted their deftness of hand and their special but primitive methods of washing the ore from generation to generation. Altogether 85,000 people are employed in the working of gold and platinum, 13,500 in naphtha, 15,000 in salt mines, and 36,000 at the blast furnaces, in manufactories, and divers other occupations connected with the mineral exploitation. In the great works there are apparatus fitted with disintegrating mills for the washing. They treat the gold obtained from the veins in the usual manner. The crushing and the enriching of the ores and amalgamation is performed by grinding mills and on amalgamated copper plates. The chemical processes for the treatment of complex ores have been recently installed—chlorination by the Plattner and the Munktel processes and cyanide process by the MacArthur-Forrest method. Platinum is met with on the Asiatic side of the mountains in the basin of the Martian River, and further towards the north in the basin of the Isse River. These places are, excepting a few spots in Colombia, which produce very little, the only regions in the world where a supply of platinum is obtained. The platinum market, however, is almost completely controlled by England. The first native bed of platinum was discovered in the Urals in 1892 in a serpentine rock. The working of platinum mines very much resembles that of gold mines, but it is even more simple, since it does not include amalgamation. The museum of the Institute of Mines, at St. Petersburg, possesses large nuggets of platinum, and other rare samples are also exhibited there, such as gold nuggets, blocks of malachite, crystals of topaz and beryl of extraordinary size; and among other different specimens from the Urals are superb emeralds and diamonds.

EXAMINATION QUESTIONS

For

Mine Managers, Mine Foremen, Fire Bosses, Etc.

EDITED BY J. T. BEARD, C. E., E. M.

Many of the questions given by the several State Boards of Examiners suggest principles which can be more satisfactorily discussed in a separate article than is advisable in an answer to an examination question, which should be as brief and concise as possible. It is the purpose of MINES AND MINERALS, to discuss in this department of "Examination Questions" the principles of practical mining upon which these questions are based, feeling sure that such articles will be appreciated by and be a help to all who are preparing themselves for mine examinations.

Mine Inspectors' Examination, Held at Des Moines, Iowa, March 5, 6, and 7, 1900.

QUES. 1.—What is meant by "motive column," and what will be its numerical value in a case where the depth of downcast is 300 feet, temperature of downcast 32° F., and temperature of upcast 48° F.

ANS.—The term "motive column" is fully explained in reply to Ques. 2, page 426, MINES AND MINERALS, April, 1900. There are two formulas, however, for motive column, the one giving the value of the motive column in terms of the downcast air, and the other giving its value in terms of the upcast air. The height of these motive columns will be different since they are composed of air of different density, the former being the shorter of the two columns since it is composed of denser air. These two formulas are given and their application explained in the answer to Prize Contest Question 546, page 316, MINES AND MINERALS, February, 1900.

Applying these formulas to the example given above we have, for the motive column in terms of the downcast air at a temperature of 32° F.,

$$M = 300 \times \frac{48 - 32}{459 + 48} = 300 \times \frac{16}{507} = 9.467 \text{ ft.}$$

Again, for the motive column in terms of the upcast air, we have $M = 300 \times \frac{48 - 32}{459 + 32} = 300 \times \frac{16}{491} = 9.776 \text{ ft.}$

QUES. 2.—An airway is 7 ft. $\times$ 10 ft. in section, and 5,000 feet in length. Taking the coefficient of friction as .00000001, what pressure will be required to pass 60,000 cubic feet of air through this airway per minute?

ANS.—Applying the formula for pressure $p = \frac{k l o q^2}{a^3}$, we have, in this case,
 $p = \frac{.00000001 \times 5,000 \times 2(7 + 10) \times 60,000^2}{(7 \times 10)^3} = 17.843 \text{ lb. per sq. ft.}$

QUES. 3.—A point which may be known as B is 33 yards east of another known as A. C is 18 yards north of B, and D is 24 yards east from C. What is the distance from A to D?

ANS.— $AD = \sqrt{18^2 + (24 + 33)^2} = 59.77 \text{ yd.}$

QUES. 4.—If 40,000 cubic feet of air pass each minute through an airway 6 ft. $\times$ 8 ft. in section, while the water gauge is 1.2 inches, what quantity will pass per minute through another airway of the same length, 8 ft. $\times$ 12 ft. in section, when the power producing the ventilation is the same?

ANS.—When the power remains the same, the quantity of air in circulation varies as the expression $\frac{a}{l^3 o}$, in which a = area of airway (sq. ft.); l = length of airway (ft.); o = perimeter of airway (ft.). In the present case, the length of the airways being the same, the quantity varies as the expression $\frac{a}{l^3 o}$, and we write the proportion,

$$\frac{(6 \times 8)}{l^3 2(6 + 8)} : \frac{(8 \times 12)}{l^3 2(8 + 12)} :: 40,000 : x,$$

$$\text{or } x = 40,000 \times \frac{8 \times 12}{6 \times 8} \times \frac{2(6 + 8)}{2(8 + 12)}$$

Canceling the common factors and simplifying, we have

$$x = 40,000 \times 2 \times \frac{7}{10} = 80,000 \times .8879 = 71,032 \text{ cu. ft.}$$

QUES. 5.—The area of the piston of an engine is 500 square

inches; the mean effective pressure per square inch is 30 pounds; length of stroke 8 feet; and number of strokes per minute 20. What is the horsepower of the engine?

ANS.—The theoretical horsepower of the engine is calculated by the formula

$$H = \frac{p \times l \times a \times n}{33,000},$$

in which

p = pressure (lb. per sq. in.);
 l = length of stroke (ft.);
 a = area of piston (sq. in.);
 n = number of strokes per minute.

Substituting numerical values for these letters, we have

$$H = \frac{30 \times 8 \times 500 \times 20}{33,000} = 72.7 \text{ H. P.}$$

QUES. 6.—A fan making 50 revolutions per minute gives 4½ pounds pressure per square foot. If the speed be increased to 75 revolutions per minute, what will be the reading of the water gauge?

ANS.—It is customary to estimate the yield of a fan as being proportional to its speed. Pressure in any circulation varies as the square of the quantity. Hence, it follows that the pressure will vary as the square of the speed of the fan, or

$$50^2 : 75^2 :: \frac{4.5}{5.2} : x, \text{ or } x = \frac{4.5}{5.2} \times \left(\frac{75}{50}\right)^2 = 1.947 \text{ in. w. g.}$$

As a fact, however, the quantity of air does not vary exactly as the speed, but more accurately as the fifth root of the fourth power of the speed. That is to say, if we double the speed, we do not obtain double the quantity, but about 1.74 times the quantity. It follows from this that the pressure does not vary exactly as the square of the speed, but more accurately as the fifth root of the eighth power of the speed. That is to say, if we double the speed, we do not obtain $2^2 = 4$ times the pressure, but we obtain $2^{\frac{8}{5}} = 3.03$ times the pressure. These latter figures correspond more accurately with the results of practice, but the former is the customary method of calculation.

QUES. 7.—What horsepower engine is required to ventilate a mine working 300 men, when the water gauge stands at 1 inch?

ANS.—Assuming that 300 miners will require say 6 mules, and since the mining laws of Iowa require 100 cubic feet of air per minute per man, and 500 feet per minute per mule, we have for the required circulation in this mine $300 \times 100 + 6 \times 500 = 33,000$ cubic feet of air per minute. If the water gauge is 1 inch, the horsepower of the engine required for this ventilation, assuming an efficiency of 60 per cent. for the engine is calculated as follows:

$$\text{w. g.} = \frac{33,000 \times 1 \times 5.2}{.60 \times 33,000} = 8.66 \text{ H. P.}$$

QUES. 8.—If the modulus of the machinery producing ventilation be 62, what horsepower must be performed in maintaining a volume of 120,000 cubic feet of air per minute, with a water gauge of 1.39 inches?

ANS.—Assuming that by "modulus" is meant the efficiency of the ventilating machinery, this being 62 per cent., the horsepower concerned in this circulation is calculated as follows:

$$\frac{120,000 \times 1.39 \times 5.2}{.62 \times 33,000} = 42.4 \text{ H. P.}$$

QUES. 9.—If 50,000 cubic feet of air pass per minute through an entry having a sectional area of 20 square feet, and a rubbing surface of 20,000 square feet, what is the reading of the water gauge?

ANS.—The water gauge in this example is calculated as follows:

$$\text{w. g.} = \frac{.0000000217 \times 20,000 \times 50,000^2}{20^3 \times 5.2} = 26.08 \text{ in.}$$

QUES. 10.—If by the application of 42,000 units of work, a current of 31,500 cubic feet of air is set in motion, in a mine, how many units of work are required to circulate 70,000 cubic feet of air in the same mine?

ANS.—Since in any circulation the power or work producing the current varies as the cube of the quantity of air in circulation, we have $31,500^3 : 70,000^3 :: 42,000 : x$, or $x = 42,000 \times \left(\frac{70,000}{31,500}\right)^3$

$= 42,000 \left(\frac{20}{9}\right)^3 = 42,000 \times 10.974 = 460,908$ units of work.

QUES. 11.—With a fan 8 feet in diameter, making 250 revolutions and passing 62,000 cubic feet of air per minute, when the water gauge stands at 1 inch, what is the equivalent orifice?

ANS.—The equivalent orifice of this circulation is calculated as follows:

$$a = \frac{.00038 \times 62,000}{1} = 23.56 \text{ sq. ft.}$$

QUES. 12.—100,000 cubic feet of air pass through an airway 6 ft. $\times$ 5 ft. sectional area, and 10,000 feet long. This is divided into three splits, one of which is 6 ft. $\times$ 6 ft. in section, 2,000 feet long; another 6 ft. $\times$ 5 ft. in section, and 4,000 feet long; and the

third 6 ft. $\times$ 4 ft. in section, 6,000 feet long. What quantity of air will pass each split while the pressure remains the same?

Ans.—The main airway 6 ft. $\times$ 5 ft., 10,000 feet long, may be ignored in this calculation, assuming only that the three splits mentioned start from the same point, at the end of this main airway, and that the pressure is the same at the mouth of each of these splits. The quantity passing in each split will then be

proportional to the expression $a\sqrt{\frac{a}{l}}$, and we find as follows:

$$\begin{array}{l} \text{Split A, } a\sqrt{\frac{a}{l}} = 36\sqrt{\frac{36}{48,000}} = .9859 \\ \text{Split B, } a\sqrt{\frac{a}{l}} = 30\sqrt{\frac{30}{88,000}} = .5539 \\ \text{Split C, } a\sqrt{\frac{a}{l}} = 24\sqrt{\frac{24}{120,000}} = .3394 \\ \text{Total, } 1.8792 \\ \text{Split A} = \frac{.9859}{1.8792} \times 100,000 = 52,463 \text{ cu. ft.} \\ \text{Split B} = \frac{.5539}{1.8792} \times 100,000 = 29,475 \text{ cu. ft.} \\ \text{Split C} = \frac{.3394}{1.8792} \times 100,000 = 18,062 \text{ cu. ft.} \\ \text{Total, } 100,000 \text{ cu. ft.} \end{array}$$

QUES. 13.—In what time can an engine of 40 effective horsepower pump 4,000 cubic feet of water from a depth of 360 feet?

Ans.— $4,000 \times 62.5 \times 360 = 90,000,000$ foot-pounds, total work. Each horsepower equals 33,000 foot-pounds per minute, then, since 40 horsepower is effective for the performance of this work, we have for the required time, $\frac{90,000,000}{40 \times 33,000} = 68.18$ minutes.

QUES. 14.—In a certain entry the velocity of the ventilating current is 10 feet per second. What will be the velocity of the air current in another entry of double the length, if the area and the water gauge are the same as in the first entry?

Ans.—In any given airway, when the pressure remains constant, the velocity varies as $\sqrt{\frac{a}{l}}$, in which a = area, l = the length, and o = the perimeter of the airway. In this example, however, the area and, presumably, the perimeter are the same in each entry; and the lengths of the entries are to each other as 1 : 2. Hence, we have

$$\sqrt{2} : \sqrt{1} :: 10 : x, \text{ or } x = \frac{10}{\sqrt{2}} = 7.07 \text{ ft. per sec.}$$

QUES. 15.—If the indicated horsepower of an engine operating a fan is 40, while the horsepower of the air is only 28, what is the percentage of useful effect of the engine?

Ans.—The percentage of useful effect of this engine is calculated as follows:

$$\frac{28}{40} \times 100 = 70\%.$$

This is the mechanical efficiency of the engine and ventilator combined.

QUES. 16.—With a fan of 30 horsepower, from which you are obtaining only 50 per cent. useful effect while the water gauge stands at 2.3 inches, what quantity of air per minute should you get?

Ans.—Since there is 50 per cent. of useful effect in this case, the horsepower effective upon the air is $30 \times .50 = 15$ horsepower. The quantity of air passing with this power and a water gauge of 2.3 inches, is calculated as follows:

$$q = \frac{15 \times 33,000}{2.3 \times 5.2} = 41,388 \text{ cu. ft. per min.}$$

QUES. 17.—A furnace is capable of producing 42,670 cubic feet of air when operated alone, but when combined with a fan, the two produce 46,706 cubic feet per minute. What will the fan produce by itself?

Ans.—Since the furnace and the fan will each perform the same amount of work whether running together or singly; and since the work is always proportional to the cube of the quantity in any given airway, we have

$$q_1 = \sqrt[3]{Q^3 - q^3} = \sqrt[3]{46,706^3 - 42,670^3} = 28,923 \text{ cu. ft. per min.}$$

QUES. 18.—If 40,000 cubic feet of air per minute pass through an airway 6 ft. $\times$ 6 ft. sectional area, with a water gauge of 1.4 inches, what amount of air will pass through another airway of the same length, 8 ft. $\times$ 8 ft. in section, when the pressure is the same?

Ans.—The pressure remaining the same, the quantity of air

in circulation varies as the expression $a\sqrt{\frac{a}{l}}$. Since the airways have the same length, in this example, we have

$$36\sqrt{\frac{36}{24}} : 64\sqrt{\frac{64}{32}} :: 40,000 : x,$$

and

$$x = 40,000 \times \frac{16\sqrt{\frac{2 \times 2}{9}}}{3} = 82,112 \text{ cu. ft. per min.}$$

Since these airways are similar airways, the pressure remaining the same, we may apply the law that the quantity of air in circulation will vary as the square root of the fifth power of the similar sides, thus

$$\sqrt[5]{6^5} : \sqrt[5]{8^5} :: 40,000 : x,$$

$$\text{or } x = 40,000 \times \sqrt[5]{\left(\frac{8}{6}\right)^5} = 82,112 \text{ cu. ft. per min.}$$

QUES. 19.—How much work is done in raising 300 tons of coal up an incline 2,700 feet long, and rising 1 foot in 3, when the friction of the cars adds 40 per cent. to the load?

Ans.—It will be necessary, in answering this question, to assume the number of trips hauled or the load hoisted in each trip. Assuming this work is done in making 25 trips, we have $\frac{300}{25} = 12$ tons per trip. This is the weight of the coal hoisted in each trip, and to this must be added the weight of the mine cars, which we may assume to be one-third of the weight of the coal hoisted or $\frac{12}{3} = 4$ tons per trip. Then the weight of the loaded trip equals $12 + 4 = 16$ tons. The next step is to determine the size of the rope required for this hoist, inasmuch as the gravity pull of the rope and its friction upon the incline must be added to the gravity pull of the loaded trip, in order to obtain the total load upon the rope. We find the tension upon the rope due to the gravity pull and the friction pull of the loaded trip and the rope as follows:

$$T = (W + wl) \times \left(\sin a + \frac{\cos a}{40} \right),$$

in which W = the weight of the loaded trip;
 w = the weight of the rope per lineal foot;
 l = the length of the incline;
 a = the angle of the slope, or the inclination of the plane.

It will be observed that the gravity pull is always obtained by multiplying the load by the sine of the slope angle; while the friction pull is found by multiplying the load by $\frac{1}{40}$ th of the cosine of the slope angle since the friction is $\frac{1}{40}$ th of the normal pressure of the load upon the plane. In this case, the incline rises 1 foot in vertical height, for each 3 feet of horizontal distance, the tangent of the slope angle being $\frac{1}{3} = .3333$. We have, therefore, for the slope angle in this case, $a = 18^\circ 26'$; and $\sin a = .3162$, $\frac{\cos a}{40} = .0237$. Assuming a weight of rope equal to

1.58 pounds per foot, and substituting the given values, we have $T = (16 \times 2,000 + 1.58 \times 2,700) \times (.3162 + .0237) = 36,266 \times .3399 = 12,327$ pounds; or, say 6 tons. Using a plow-steel wire rope, having six strands of seven wires each, we find the breaking strain of a 1-inch rope, weighing 1.58 pounds per foot, to be 42 tons, which will give, if we use this rope, a factor of safety of about 7. If we multiply the tension, or pull upon the rope, by the distance through which this pull is exerted in hoisting the 300 tons of coal up this incline, we will obtain the total work performed in hoisting this amount of coal. Thus, calling the total work U , we have $U = 12,327 \times 2,700 \times 25 = 832,072,500$ foot-pounds.

QUES. 20.—If 10,000 cubic feet of air pass each minute into a mine having two splits, one of which is 4 ft. $\times$ 12 ft. in section and 6,000 feet long, and the other 6 ft. $\times$ 8 ft. in section and 10,000 feet long, how will the current be divided?

Ans.—This example is solved in the same manner as Ques. 12 above. We first calculate the value of the expression

$a\sqrt{\frac{a}{l}}$, for each split as follows:

$$\text{Split A} = 48\sqrt{\frac{48}{2(4+12)6,000}}$$

$$\text{Split B} = 48\sqrt{\frac{48}{2(6+8)10,000}}$$

Since these values for each split are merely used as ratios the work may be much simplified by first canceling all factors

common to each split. Doing this we obtain the following values:

$$\text{For split A, } \frac{1}{\sqrt{8 \times 3}} = .204$$

$$\text{For split B, } \frac{1}{\sqrt{7 \times 5}} = .169$$

$$\text{Total, } .373.$$

The quantity of air passing in each split is then,

$$\text{Split A, } \frac{.204}{.373} \times 10,000 = 5,469 \text{ cu. ft. per min.}$$

$$\text{Split B, } \frac{.169}{.373} \times 10,000 = 4,531 \text{ cu. ft. per min.}$$

$$\text{Total, } 10,000 \text{ cu. ft. per min.}$$

Ques. 21.—If 33½ per cent. be allowed for friction, what weight can be lifted by a pair of first-motion engines, having cylinders 16 in. × 32 in. and a drum 8 feet in diameter, when the steam pressure is 60 pounds per square inch?

Ans.—Having a cylinder pressure of 60 pounds per square inch and the diameter of the cylinder being 16 inches, the total cylinder pressure is $.7854 \times 16^2 \times 60 = 12,064$ pounds. Since the length of the stroke is 32 inches, the crank arm upon the drum shaft is $\frac{32}{2} = 16$ inches, and the moment of the cylinder pressure at the center of the drum shaft will be $12,064 \times 16$. Since the diameter of the drum is $8 \times 12 = 96$ inches, the moment of the load (W), upon the winding rope, will be $W \times \frac{96}{2} = 48 W$. These two moments must be equal to each other, and we have for the total load (W), including friction, $W = 12,064 \times \frac{16}{48} = 4,021$ pounds. Since 33½ per cent. of this load is absorbed by the friction of the hoist we have for the net load hoisted $4,021 \times \frac{2}{3} = \text{say } 2,680$ pounds.

Ques. 22.—9,000 cubic feet of air per minute pass through a regulator, at which the difference of pressure of the two sides is equal to $\frac{1}{16}$ of an inch of water gauge. How far is the regulator shutter open, if it is 1 foot in depth?

Ans.—The usual method of estimating the size of opening in a box regulator, when the difference of pressure between the two sides of the regulator is given in inches of water gauge, is by using the formula,

$$a = .00038 \frac{Q}{\sqrt{i}}$$

in which a = the area (sq. ft.) of the opening;
 Q = quantity of air passing (cu. ft. per min.);
 i = water gauge (in.).

Substituting the given values in this equation, we have for the area of the opening

$$a = .00038 \frac{9,000}{\sqrt{.7}} = 4.088 \text{ sq. ft.}$$

If the height of the opening is 1 foot, then the width of the opening will be $\frac{4.088}{1}$, or 4.088 feet.

Ques. 23.—The entry of a mine is 7 ft. × 10 ft. in section and 6,720 feet long. What is the velocity of the ventilating current passing through this entry, when the water gauge stands at 2 inches?

Ans.—The velocity in this case is calculated from the formula $v = \sqrt{\frac{p a}{k s}}$, or since here $p = 5.2 \times 2 = 10.4$ pounds, we have for the required velocity in this case,

$$v = \sqrt{\frac{10.4 \times 70}{.0000000217 \times 2(7 + 10)6,720}} = 383.2 \text{ ft. per min.}$$

Ques. 24.—What should be the quantity of air for a mine producing 300 tons of coal per day? What should be the effective horsepower of the ventilator required to furnish it, when the water gauge stands at 1 inch?

Ans.—The average output of coal per miner per day is, say 2.5 tons in Iowa; then $\frac{300}{2.5} = 120$ miners required to produce this quantity of coal per day. To this number must be added, say 120 helpers or loaders, and 10 company hands, including drivers, timbermen, trackmen, trappers, and cagers. There will also be required, say 3 mules in this mine. The quantity of air required by law for the ventilation of such a mine would be $100 \times (240 + 10) + 500 \times 3 = 26,500$ cubic feet as a minimum quantity. We should estimate, however, upon a circulation of 28,000 or 30,000 cubic feet of air per minute. The effective horsepower for this circulation is calculated as follows:

$$\frac{30,000 \times 1 \times 5.2}{33,000} = 4.7 \text{ H. P.}$$

Changes Steel May Undergo in Tempering.

Many rules are laid down for the tempering of tool steel, and these do not in all cases agree. There are, in fact, many different methods employed by different blacksmiths, and numerous modifications of these methods are also in use, both in the tempering of drill steel and pick steel. In very few cases will two blacksmiths agree throughout in their ideas of the heating and tempering of steel. Each has an experience of his own, and each may be equally successful in the tempering and handling of the material of his work. It may be said that no hard and fast rule can be laid down for the edification of the unlearned. The tempering of steel is an art that must be acquired by experience, directed by a thorough technical knowledge both of the material in hand, and of the changes which it is liable to undergo in the several operations to which it is subjected.

We will refer briefly to the difference existing between cast iron, steel, and wrought iron in reference to the amount of carbon which these contain. It is well known that cast iron represents the highest degree of carbonization of these three forms of iron, containing usually over 3 per cent. of carbon; cast steel may contain from .06 per cent. to 1.5 per cent., while wrought iron, being the purest form of iron, contains only from .02 per cent. to .10 per cent. There are, however, no exact lines of division between these three forms of iron, since one form easily grades into another, and the characteristic features of the several forms mentioned are found more or less modified in all. In general, we associate with cast iron the idea of brittleness and a small amount of elasticity and ductility; while, on the other hand, wrought iron presents to us the characteristics of toughness and ductility. Steel gives us, at once, the idea of hardness and elasticity; it presents neither the brittleness of cast iron, nor the toughness of wrought iron; but combining these, gives us a material that is hard and elastic. While there are other elements which enter into and modify the constitution of iron, and adapt it to various purposes, the presence of carbon is perhaps more important, in the tempering of steel, than that of any other known element.

It is well known that from the same material may be produced cast iron, steel, or wrought iron according to the stage of the process at which the operations are arrested in their manufacture. In a general way, we understand that the heating of iron is attended to a greater or less extent with the burning of the carbon which it contains. In the manufacture of steel and malleable iron, operations are introduced that hasten the oxidation or burning out of this carbon. It is of importance to the blacksmith, however, to understand clearly that the same oxidation goes on, to a less extent, upon the surface of the iron which is heated in the forge. It is customary to see a good smith, when introducing a bar of steel into the forge, settle down his fire and carefully cover the steel. This is for the purpose of preventing the access of air to the hot bar, which would cause more rapid oxidation of the carbon in the heated surface of the steel. When a bar of iron is heated red hot and allowed to cool slowly in the air, this process of oxidation continues during the cooling; and the surface of the metal is decarbonized to a greater or less extent, rendering it soft and tough, or giving it the features of wrought iron. On the other hand, when a bar of iron is to be hardened, or as we say, given a high temper, it is heated to a bright cherry red and plunged at once into a bath to cool it suddenly; thereby preventing the oxidation of the carbon upon the surface of the metal. This gives a hardness and durability to the iron that is of great importance in the manufacture of tools. This operation of hardening is usually the first operation performed upon drill and pick steel, by the smith. It is, however, often omitted by other smiths, but we think the omission tends, in the long run, to deteriorate the steel, and reduce the general temper of the iron. The better practice is to restore the temper of the bit, when sharpening.

In the hardening of steel for cutting purposes, it is important that the bath should be of sufficient volume that the cooling be done rapidly and without danger of raising the temperature of the bath; otherwise, the hardening of the steel will not be accomplished in a thorough manner. This bath may be either pure water—rain water or soft water being preferred—or a more or less concentrated brine, or a bath of common black oil. The action of the brine or of the oil when substituted for water as a cooling bath, may be, to a certain extent, to reduce the rate of cooling; but the chief efficacy of these lies in their prevention of oxidation, during the cooling, which takes place to a limited extent in the use of water, which always contains a certain amount of air in solution. In the use of oil, there is a certain amount of carbon absorbed by the surface of the hot iron, which thereby becomes slightly carbonized and toughened as well as hardened, during the sudden cooling. This action of the oil during the cooling, is very important, in the tempering of drill steel particularly. The question was asked not long since, if hot water would be as "efficacious as oil in the cooling

of steel in tempering"? The idea being expressed that the time of cooling would be lengthened, when hot water is employed, and the same effect produced as in the use of oil, for this purpose. Our reply to this question is that the effect would not be the same, as the efficacy of the oil consists in the carbonization of the surface of the steel, during the cooling.

In the sharpening and tempering of pick steel, regard must be had by the smith to the character of work for which the tool is to be employed. Picks that are to be used in soft coal or coal of medium hardness, require toughness more than high temper. These should have a longer point than when employed in harder coal, or in rock, or among sulphur balls. Where the hardness of the material to be picked is considerable, the point of the pick should be more blunt, and its temper raised. A good miner will have on hand several kinds of picks, which he will use according to the work in hand. The point of the pick should not be drawn so fine that it tends to bind, in the coal, and takes an effort to remove it, when cutting; neither should it be so blunt as not to cut well. Different styles of points will be found applicable to different kinds of coal, and these can only be determined by the experience of the miner.

As the method of hardening, reheating, and tempering has been fully explained in a previous article (page 188, MINES AND MINERALS, November, 1899), we will not repeat the process here; the aim of this article being to draw more particular attention to what constitutes the difference in the several forms of iron; and how one form may readily be modified to assume the characteristics of another form, without due care in the handling of the hot iron.

Haulage.

(Continued from July Issue.)

Rope Haulage on Level Roads.—The subject of rope haulage upon roads that are practically level, in distinction from gravity- and engine-plane systems is divided into two general systems: (1) Tail-rope haulage. (2) Endless-rope haulage. These two systems, while they may be used at times interchangeably under the same conditions, yet each has its own adaptation to particular conditions. There is much in the consideration of the subject of rope haulage that requires experience in the operation of the system, in order to appreciate fully the several points in regard to each system. In general, a tail-rope system of haulage is better adapted to seams in which the haulage roads present various grades. This is particularly the case in many of the seams of the central basin. The coal deposits, in many localities are not continuous deposits of uniform thickness and inclination, but present numerous changes in the physical characteristics of the seams, particularly with reference to the grades of haulage roads in those seams.

In the installation of any system of mechanical haulage, it should always be the aim and endeavor to straighten the roads, and to render the grades as uniform as possible by cutting the hills and filling low places. When this has been done, however, there often remain numerous short up and down grades in the haulage road. The result of these numerous occurring grades is to throw irregular loads upon the winding engine. These varying loads thrown upon the engine in no particular order, are less easily controlled in the operation of an endless-rope system than in a tail-rope system. This is true from the fact that in the endless-rope system the loads may be all upon a down grade at once, or it may occur that they are evenly divided. The latter condition would be very favorable to the operation of the system; but there is no regularity with regard to the load, and the engineer finds great difficulty often in the proper regulation and control of his engine.

The Tail-Rope System of Haulage.

In the operation of the tail-rope system, the loaded trip occupies one place in the haulage road, instead of being distributed along its entire length, as in the endless-rope system. The trip may consist of anywhere from 5 to 25 cars, or even a greater number than this. In this system, two ropes are employed, the one called the *main rope*, running from the engine into the mine, draws the loaded trip out; while the other, called the *tail rope*, running from the engine into the mine and passing over a return sheave at the farthest point inbye of the haulage road, is used to draw the empty cars back into the mine, as well as to restrain and regulate the velocity of the loaded cars while they are being drawn out of the mine. The heaviest burden of haulage thus falls upon the main rope, which in most cases is made the heavier of the two ropes. The tail-rope

system is more pliable than the endless-rope system and possesses the advantage that the engineer is better able to control the working of the system and of his engine throughout the entire trip. The rigidity of the latter system often throws an undue strain upon the rope, and varying loads upon the engine. The operation of the tail-rope system, however, requires considerable care and tact on the part of the engineer in the control of the drum, from which the tail rope is winding off. This drum is uncoupled from the engine shaft during the unwinding, and its motion is controlled by the brake. Only sufficient slack must be given to the tail rope as is required by the movement of the loaded trip.

The general points of interest in regard to the conducting of the ropes through the mine passages will be described later in an article "Rope Transmission in Mine Haulage." It remains to speak, in this article, of the manner of conducting the winding rope from the engine to the shaft bottom, and a few other details in reference to the location of the inside parting, return sheave, etc., and to illustrate the calculation of the power required for any given tail-rope haulage.

Conducting the Ropes Into the Mine.—There are several methods of carrying the ropes from the engine into the mine. The haulage ropes are often taken down a compartment or manway in the hoisting shaft. When this is not practicable, drill holes are sometimes put down from the surface to a point in the haulage road near the shaft bottom (Figs. 1 and 2). The drill holes for this purpose are cased from top to bottom with a 2½- or 3-inch casing. Large sheaves are placed in position over the hole, and at the bottom of the hole, in the roof of the haulage road. To support the sheave pulley in the roof of the haulage road, a special heavy framing is necessary (Fig. 2). The wear upon the rope by rubbing upon the casing, in passing through a drill hole is not as great as would at first seem probable. The rope is kept well oiled, which decreases the friction and consequent wear.

In some cases, it is considered preferable to conduct the tail rope over the surface to a point immediately over the return sheave, at the inbye end of the inside parting. At this point, a drill hole is located and bored, and the necessary sheaves placed in position above and below. This method possesses several advantages and some disadvantages. The advantages are, a shorter rope is required; there is less wear and tear in transmission on account of the course of the rope being more direct; and the annoyance of the rollers and sheaves in the entries is avoided. The rope, however, upon the surface is exposed to the weather, and is subject to sudden changes of temperature from the warmer air of the mine to the cool outside air, or from the cold of the atmosphere to the heat of the engine room. In the transmission of a rope over the surface, large trestles are necessary in order to elevate the rope to a sufficient height to avoid any damage to cattle or otherwise.

The return sheave is shown in Fig. 3, and is located at the inbye end of the inside parting. This sheave must be firmly braced against the roof and floor, to withstand the pull of the entire loaded trip; since it may be necessary, at any time, to bring the outgoing loaded trip to a standstill at any point in the mine; or it may be necessary to pull the return trip back a short distance, upon the steepest grade in the mine. Not only must the return sheave be able to withstand the pull necessary for this work, but the tail rope itself must be of a size and strength sufficient to withstand the load thus thrown upon it. A heavy framing is usually set at the point where the return sheave is located, to support the roof and prevent a fall at this point. Two upright posts are then set, side by side, behind this framing, the upper ends of the uprights being set into the roof, and the lower ends being sunk into the floor. If necessary a heavy cross-sill is placed in the floor in front of the uprights to give them a good bearing. If the tail rope is carried over the surface and enters the mine at the return sheave, as shown in Fig. 3, these uprights should be inclined somewhat backwards, so that the reaction from the pull of the vertical and horizontal ropes shall be nearly normal to the timbers carrying the sheave. The purpose of this is to relieve the journals of the load which would otherwise be thrown upon them. When the uprights, however, are inclined in this manner a strong brace should be introduced, to prevent the foot of the upright from lifting the bottom. These braces should extend from the foot of the upright forward to a point in the roof as

FIG. 1.

FIG. 2.

shown in the figure. The location of the return sheave should be such that the tail rope may be readily carried under the empty track where this turns from the main track, to form the side track, at the parting. Suitable guide sheaves and rollers are placed between the two tracks of the parting, for this rope. The form of tail sheave shown in Fig. 4 is sometimes used, when the tail rope is conducted into the mine at the shaft, and carried along the haulageway. This sheave is located beneath the empty track, at the inbye end of the parting, but is not as convenient as the tail sheave shown in Fig. 3.

FIG. 3.

depends upon two factors only. (1) The tension upon the rope. (2) Speed of winding. In the installment of any proposed rope haulage, we should estimate upon the power which will be required under any conditions that are liable to occur. Regard must be had to the future development and extension of the haulage system, as well as to steeper grades, that may be encountered.

1. *Load Upon the Haulage Rope at the Winding Drum.*—It is customary to consider the main rope and tail rope separately in determining the loads upon each of them. The tail rope is often made the lighter of the two ropes; since, as is argued, this rope is required only to haul the empty cars back into the mine. We regard this as a serious error, for the reason that the tail rope should possess strength sufficient to enable it to control the loaded trip upon the steepest grade in the mine. It may become necessary at any time, to bring the loaded trip to a standstill upon its outward journey, or to haul this trip back a short distance into the mine. This emergency may occur upon the steepest grade of the road. The tail rope should obviously be strong enough to perform this work. The objection to making the tail rope of the same size as the main rope is practically, however, of little importance, since in the operation of the system it is customary, and we may say good practice, when it becomes necessary to order a new rope, to make the main rope, which is becoming worn, the future tail rope, and to order a new main rope. This can always be done readily when the ropes are conducted into the mine at the shaft and carried along the haulway.

Where the tail rope is carried over the surface and dropped into the mine at the tail-rope sheave, it would be necessary in order to make the change proposed, to couple the inbye end of the main rope to the tail rope, and draw it up through the drill hole at the tail sheave to the surface and back to the winding drum. In this case, the main rope will always be long enough to be used as a tail rope, and there will be a piece that will have to be cut off from it, in almost every instance; since the course of the tail rope over the surface is more direct than that below ground. It will be necessary, in the adoption of this method, when the ropes are both conducted through the haulageways, to always order a length of main rope slightly longer than that required, in order that it may be long enough to pass over the tail sheave when used as a tail rope. However, these matters are of little importance, since the estimate of the length of the rope should always be ample to provide for some splicing. We mention them here as a safeguard only. The extra length can usually be coiled away inside of the winding drum, if necessary.

In estimating the load upon the rope at the winding drum, we must consider the following factors. (a) The weight of the rope hanging in the shaft or drill hole. (b) The gravity pull due to the loaded trip upon the steepest grade in the mine. (c) The friction of the entire system, including rolling friction of the loaded trip and that of the rope.

This calculation should be made on the assumption that the rope is a tail rope, provided the steepest grade occurs when the movement of the trip is inbye. Indicating as follows:

- T = tension or pull upon rope (lb.);
- W = weight of loaded trip (lb.);
- w = weight of rope per lineal foot (lb.);
- l = length of both ropes; equals 2 times the distance from winding drum to tail sheave (ft.);
- d = vertical drop of rope (ft.);
- a = slope angle of maximum grade.

We have for the weight of rope in shaft $w d$; the gravity pull and friction pull of the loaded trip, $W \left(\sin a + \frac{\cos a}{40} \right)$; and for

the friction of the rope $\frac{wl}{40}$. We assume that the loaded trip is upon the maximum grade in the mine, whether this grade is an inbye or an outbye grade. We calculate the friction for the entire length of both ropes but assume that the gravity pulls of the rope upon the several grades balance each other. The entire length of rope is twice the distance from the winding drum to the tail sheave. It is to be observed that the weight of the descending rope does not balance the weight of the ascending rope, in the shaft, in this system of haulage, since the drum from which the rope is unwinding is always uncoupled from the drum shaft, and its motion controlled by the brake. The engine must, therefore, always lift the dead weight of the ascending rope, in the shaft. Combining the above expressions, we have for the load upon the rope,

$$T = W \left(\sin a + \frac{\cos a}{40} \right) + w \left(d + \frac{l}{40} \right).$$

From this tension or pull, the size of the rope is determined, using a factor of safety of say 4 or 5. A greater factor of safety may be used, if desired, in order to increase the time the rope will wear, or the life of the rope.

EXAMPLE.—What size of steel wire rope will be required to haul a trip of 20 mine cars, the weight of the loaded cars being 3,000 pounds each, the depth of the shaft being 300 feet, and the distance from the foot of the shaft to the tail sheave 900 yards; the maximum grade in this haulage being 10° ?

SOLUTION.—Substituting the given values in the above equation, we have for the pull upon the rope at the winding drum, in this case, assuming for the present a $\frac{3}{4}$ -inch rope weighing .88 pound per lineal foot,

$$T = 60,000 \left(.17365 + \frac{.9848}{40} \right) + .88 \left(300 + \frac{6,000}{40} \right) = \text{say } 12,300 \text{ lb.}$$

or somewhat over 6 tons.

Referring to the tables for steel haulage ropes with six strands of seven wires each, we find the breaking strain of a $\frac{3}{4}$ -inch rope, weighing .88 pound per lineal foot, is 24 tons, which will give a factor of safety of about 4. We would prefer, however, in this haulage to use a $\frac{7}{8}$ -inch or even a 1 inch rope, as a change of ropes would then be required less often.

Making the necessary corrections for a 1-inch rope weighing 1.58 pounds per lineal foot, we find for the pull upon the rope, in this case,

$$T = 12,607 \text{ lb.}$$

2. *Speed of Winding.*—The speed of winding, in any system of haulage, must be determined after considering the condition of the haulageways and the rolling stock, in connection with the grades and the desired output. The first step in this problem is to determine the size of the trip, or the number of cars or weight of coal to be hauled in each trip. The capacity of the mine cars is usually fixed to a great extent by the character of the seam; thin seams requiring cars of small capacity; poor roof requiring narrow cars; while thick seams admit of cars of greatly increased size and capacity. The number of cars that can be hauled in a trip is very largely dependent upon the character of the roadway and the rolling stock, the number and degree of curves, etc. Where track and cars are in excellent condition, trips of 25 or 27 cars may be hauled, by a careful and observing engineer. These considerations determine the weight of coal which it is advisable to haul per trip, in any given case. Having determined this, the speed of winding and the length of haul are the two remaining factors which determine the output of the mine. The speed of winding is also dependent upon the condition of the roadway and rolling stock. Under ordinary conditions of mine haulage, it is not advisable or safe to increase the speed of winding much beyond that of 12 miles per hour; although, when the track and cars are in good condition and the road fairly straight, this speed

FIG. 4.

may be exceeded to some extent in tail-rope haulage. A speed of 12 miles an hour is

$$\frac{12 \times 5,280}{60} = 1,056 \text{ ft. per min.}$$

Assuming here a speed of 12 miles per hour, the power required for haulage, in the previous example, is calculated thus,

$$\frac{12,607 \times 1,056}{33,000} = 403.4 \text{ H. P.}$$

Size of Engine.—Before we can calculate the size of engine required for this haulage, we must determine the diameter of the winding drum. We have used a 1-inch steel rope of seven wires in each strand. The minimum sheave required for this rope is a sheave of 77-inch diameter. The diameter of the drum must, therefore, not be less than 77 inches, and we will assume for its diameter 80 inches.

Then, $\frac{1,056 \times 12}{80 \times 3.1416} = 50.416$ revolutions per minute, for the speed of the drum. If we make the ratio of gearing $\frac{\text{diam. of drum gear wheel}}{\text{diam. of pinion}} = \frac{3}{1}$, the engine will be required to make $50.416 \times 3 \times 2 = 302.5$ strokes per minute.

Then, assuming a mean effective cylinder pressure of, say 50 pounds per square inch, and using the formula given upon page 379, *MINES AND MINERALS*, March, 1900, making the ratio between the diameter of cylinder and length of stroke 1, we have for the diameter of cylinder,

$$d = \sqrt[3]{\frac{2LD}{pr_1}} = \sqrt[3]{\frac{2 \times 12,607 \times 80}{50 \times 1 \times 3}} = 23.78 \text{ in., or, say 24 in.}$$

Hence, the size of the duplex second-motion engine required for this haulage, will be 24 in. $\times$ 24 in.; speed 302.5 strokes per minute.

Electrically Operated Coke "Larries."

The extraordinary activity of the coke industry, due to the increased demand for coke in the iron and steel manufactures, illustrates again the law of supply and demand, the latter being so much greater than the former that it would be difficult to find an idle oven, and hundreds of new ovens are being rapidly pushed to completion. The coke manufacturer will, for some time to come, find a ready market for his maximum output, and any auxiliary that will facilitate, and at the same time cheapen, production should

receive a most welcome reception. This is a general statement true of every line of manufacture, and is characteristic of American manufacturing methods, the enterprising producer having small compunctions about discarding time-honored apparatus and systems for more modern and efficient equipments.

The manufacture of coke requires a certain minimum time, usually 48 hours for "furnace coke" and 72 hours for "foundry coke," but the quality of the coke suffers if the processes are too closely curtailed. The by-product oven is by no means an assured success, although interesting developments may be expected in that direction in the future. It is obvious, therefore, that radical improvements are immediately possible in the methods of handling the coal and coke, rather than in the processes which take place in the ovens themselves, therefore some method of charging the ovens more quickly seemed necessary. Due to the conditions under which the larry has to operate, at first there seemed to be little chance of improvement at this point and the owners of coal mines operating coke ovens did not see any promise of better results by the application of electricity to the operating of the larries, but practical experience has shown that the electrically propelled larry is the means of a large saving in both time and labor, and the results obtained from the several electric larries in operation are most gratifying. The equipment consists of a standard railway motor, of the enclosed type mounted on one of the axles, controller, and trolley, and may be applied to larries at present

drawn by animal power, it being unnecessary to design a special larry adapted for the electrical equipment. The control is so perfect that when about to discharge its load into the ovens, the larry may be moved in either direction literally "an inch at a time," and a much higher speed is possible than with horses or mules. The result is a surprising saving in time in hauling from and returning to the tipple, and in discharging the coal at the ovens. The "trolley" or "third rail" system, preferably the latter, may be used to convey the power to the motor, and the approaches to the ovens may be much more cheaply constructed, as it is unnecessary to provide a path for the horses or mules.

One electrically equipped larry with its operator will easily do the work of two mule larries with their drivers, and when the conditions permit, the electric larry may supply the motive power for other larries, which, operated as "trailers," may be dropped at the proper places, having been loaded at the tipple, and picked up on the return, in the meantime having discharged their loads into the ovens. The increased adoption of electric mining locomotives and electric motors for driving pumps, hoists, car conveyors, blowers, etc., should be considered in connection with the installation of a dynamo for the operation of coke larries, but even if the conditions are such as to debar other applications of electricity, the investment will show a very good return. At many mines generating plants are already installed, in which cases the additional investment would be very small indeed, and the saving in cost of operation would soon pay for the electrical equipment of the larry. The General Electric Co. offers for this work its standard railway motors and magnetic blow-out controllers, embodying the results of years of experience in the field of electric traction. The many advantages of using standard apparatus are obvious, and the subject is one that merits careful investigation on the part of the coke manufacturer.

While the electric larry possesses many points of superiority, the best argument in its favor is the consequent reduction in expenses. That such a reduction is effected is clearly shown by the following figures, which were submitted by a prominent coke manufacturer:

Cost per oven, horse haulage	.0583
Cost per oven, operation electric	.0829
Cost per oven, power-house expenses	.0058— .0887
Net saving per oven	.0196

It should be noted in this case that the saving amounts to 33.5 per cent. of the cost per oven of horse haulage.

Mines and Mining in Yavapai County, Arizona.

The prediction of Humboldt, that the mineral wealth of the world would be found in Arizona and New Mexico seems to be verified today. The correctness of that opinion seems to have been demonstrated. Mines that have been idle for years are once more resounding with the miner's pick and shovel, and a general waking up and activity is noticeable throughout the mining districts. More gold has been produced than ever before in the history of the county, and, what is even better, mining men have finally realized that this is the country of deep mining. The completion of the North and South Railroad has solved the problem of working the mines economically, and the industry is now entering upon its greatest era. New capital is coming in to develop the great properties of the county, and the production of the precious metals is increasing daily.

With legitimate mines there has come a change in the scene, and the old has been pushed aside for the new, the benefit of which is today attested in this vicinity by the number of men on the ground and the manner in which they are operating. It is such an improvement over the played-out past, and the country is now being so firmly and legitimately handled in the practical and energetic work that goes with deep mining as to give us greater consideration, probably, than any other section of the Southwest.

The past five years have seemingly solved the future of this county as a mining section, and if only one-half of the mines being developed prove successful, Yavapai will be the most prosperous field for mining of any subdivision of the Union. Although one of the oldest mining sections in Arizona, it is nevertheless, in a practical sense, the newest.

Ten years ago there were not half a dozen gold claims in this section that had a 250-foot shaft, and in silver mines not many more. Today, in any district the opposite prevails, and when we look around and size up the miles of underground shafts and drifts in the United Verde, the 2,400-foot main shaft in the Congress, the thousands of feet of the Crowned King, the McCabe, the Jessie, the Empire, the Senator, the Poland Hamilton, Del Pasco, the Gladiator, the Favorite, the Peery, the Henrietta, the Accident, and especially the Planet Saturn, that has struck it at 1,000 feet richer than ever, the Johnson mine, and dozens of good prospects in the vicinity of Rich Hill in Weaver district, besides many others, we realize that the country asks to be "showed up."—Report of the Governor of Arizona.

NEW INVENTIONS.

EDITED BY H. M. LANE, M. E.

Complete specifications and drawings for any of the following patents can be obtained from the COMMISSIONER OF PATENTS, WASHINGTON, D. C., at the following rates:

Single copies.....	5 cents each.
Copies by subclasses.....	3 cents each.
Copies by classes.....	2 cents each.
An entire set of patents.....	1 cent each.

CRUSHING MILL.

No. 650,097. M. J. E. ROTTER, CHICAGO, ILL. Patented May 22, 1900. This invention relates to a device for adjusting the crushing space of a gyratory crusher, and is illustrated by the accompanying figures. The

adjustment is accomplished by raising and lowering the spindle D with its crushing head D'. This is accomplished by means of a pair of cams H and H', one of which is shown in detail in Fig. 2. One of the cams H is provided with worm teeth q about its outer periphery, and these teeth are engaged by the worm P so that both cams and their connecting shaft S can be rotated at will. The yoke I has rollers riding in the cams on each side, and is carried up and down by the cams. This yoke supports a movable sleeve K having slots l' through which the shaft S passes. This sleeve carries the ordinary

thrust bearing k which supports the shaft D. One of the special advantages claimed for this device is that it is compact, and does not require a large amount of space below the crusher.

COAL SEPARATOR.

No. 650,120. CHARLES W. ZIEGLER, SCRANTON, PA. Patented May 22, 1900. The slate picker covered by this patent is illustrated by the accompanying figures, in which 7 is an inclined perforated plate over

which coal and slate slides to the picker. The picker proper is composed of inclined plates 5 having serrations or projections 6 on the upper face, as shown more clearly in Fig. 2. These plates 5 are attached to blocks 7 which are adjusted separately by means of bolts 8. At one edge of the blocks, pipes or tubes 12 are inserted so that the plates butt against them and there is a small space left between the tube and the upper edge of the next plate. This space is partially closed by the adjustable slide 15, the upper edge of which is turned down as shown. The object of this

downward bend at the upper edge of the plate is to prevent any thin pieces of slate from lodging between the plates 5 and 15. The coal attains a sufficient momentum so that it jumps the space between the tube and the shield 15 and passes on down over all the spaces to the bottom of the machine, where it is discharged through the chute as shown. The slate falls through the spaces below the tubes 12 into the chute 2. The plate 7 in the receiving chute is arranged so that its angle may be changed by means of a series of levers 25 and a hand lever 24, and the angle of the plates 5 may be varied to a certain extent by raising or lowering the supporting piece 26, which is accomplished by means of a set of links and levers on the outside of the machine.

MACHINE FOR UNDERCUTTING COAL.

No. 651,768. A. OCHTINSKY, ROCKVALE, COL. Patented June 12, 1900. The machine covered by this patent is shown in Figs. 1 and 2. The mechanism is supported between two columns E which are provided

with sliding pieces a. These sliding pieces are connected across the top by the yoke D, having a central pin d to engage with the roof. The machine is provided with wheels T for removing it from one place to another, and with spikes x for securing it to the ground in any desired position. These spikes are upon bars d carried by the ratchet wheel K so arranged that the machine may be rotated about a central vertical axis by means of the ratchet M. The picks are mounted upon bars O having a telescopic portion g so arranged that they can be extended. This portion g works through the guide M'. The picks are operated by means of cranks upon a shaft in front of the machine. The shaft is driven by the pinion m from the gear W which, in turn, may be driven by a crank from the hand wheel G or by means of the lever v and the pitman q. All of the operating mechanism is mounted upon the slide l, which can be moved forward in the frame L by means of suitable ratchets, so as to force the cutters to their work. The machine is wheeled from place to place upon the wheels T by means of the handles J.

OPERATING MECHANISM FOR STONE OR ORE CRUSHERS.

No. 650,121. W. H. BAXTER, HARBURG, ENG. Patented May 22, 1900. This patent covers an especial method of supporting the shaft in a crusher of the Blake pattern, and is fully illustrated by the accompanying figure. In place of

mounting the driving shaft G in solid bearings upon the frame A it is mounted in bearings upon the lugs H, which are attached to the movable jaw C. The shaft G is provided, as shown, with an eccentric J and connected with the toggles M by means of the pitman E. The result of this arrangement is that the movable jaw has force applied to it not only by the toggles M but also through the lugs H from the driving shaft. The inventor claims to thus reduce the amount of power necessary for crushing the material. He also claims the right to apply this principle to punches, shears, and similar machines.

ROCK-DRILLING ENGINE.

No. 651,487. J. G. LEYNER, DENVER, COL. Patented June 12, 1900. This patent has two objects in view, one is to provide a means of forcing

water or other similar liquid in combination with the operating fluid of the machine (which may be steam or air) down through the center

of the drill and bit so as to wash the cuttings from the hole. In the accompanying figure, 22 represents the bit, through which is arranged the hole 22 D. The tube 51 passes down through the drill piston and other mechanism and connects with the center of the drill 22, the water being introduced through the opening 70 from the chamber 63 and the flow controlled by the valve 62. The drill has the ordinary standard feed mechanism, consisting of a crank and a feed screw for removing the entire drilling engine forward upon its mountings. The drills are provided with lugs 21 and are introduced into the machine through the slots in the piece 4. After they are introduced, the piece 4 is partially rotated so as to close the slots through which the lugs entered. The other novel feature of this machine, aside from the water feature, consists in the fact that the drill 22 is not connected rigidly to the piston 47, but the piston operates the piece 8 by means of the hammer bar connected to the end of the piston and the interposed spring washers, and by this means operates the drill, the piston being free to return without having to drag the drill with it. A small portion of the air in the cylinder at the end of the stroke is forced from the port 33 through the spring relief valve 41 into the port 36 which communicates with the space 20 at the head of the drill. This air forces its way around the tube 51 and mingles with the water which has passed down through the tube into the top of the drill 22, so that the mixture of air and water passes down through the drill together.

ROCK CRUSHER.

No. 650,105. E. C. BACON, NEW YORK. Patented May 22, 1900. This invention relates to a crusher of the Blake type, and consists in improvements in the pitman and the manner of securing the various parts so as to prevent their becoming displaced. It is illustrated in the accompanying figures, in which A is the crushing frame of ordinary construction. The pitman D is of special design to enable it to resist the tension to which it is subjected, and at the same time to reduce the weight to a minimum. Fig. 3 shows a detail of the pitman which will make the upper portions of its construction plain. Instead of having a solid casting it is composed of two webs D² which are practically tangent to the eccentric head or strap at the top, and are united at the bottom so as to form a support for the toggle joints E. These webs D² are connected by transverse webs D⁴ in order to secure additional stiffness and strength. The head of the toggle is provided with a special oiling pocket having a hinged cover with a suitable device for securing the same, as is clearly shown in Figs. 2 and 3. The toggle plates H rest in bearings E on the end of the pitman, and are secured from longitudinal movement by lugs near their center, which fit into corresponding recesses and bearing pieces E. The bearing pieces E are held in place by wedges F secured by a through bolt G, and at the other end of the toggle plates similar bearing pieces are also held in place by wedges and bolts as shown in Fig. 1. The movable jaw C' oscillates upon the shaft C. In order to prevent longitudinal travel of the shaft it is provided with pins C² which fit into the bearings and caps upon the frame A, thus preventing the shaft either from rotating or traveling longitudinally. The filling or cheek plate K of a crusher usually wears rapidly, and also sometimes gives trouble by working loose and thus allowing the fixed plate A² to play up and down. To secure this plate firmly in position, and at the same time allow its ready renewal, the follower piece K' is introduced, which is bolted to the frame K

of the crusher. The bolt K² which secures the follower piece passes through slots in both the follower piece and the crusher frame, these slots being placed at right angles so that there is sure to be an opening at their intersection through which the bolt can pass, even though the castings themselves may be quite badly out of shape.

ORE CONCENTRATOR.

No. 650,673. W. G. DODD, SAN FRANCISCO, CAL. Patented May 29, 1900. The concentrator covered by this patent is of the movable or shaking-table type usually called vanners, and is illustrated by Figs. 1 and 2. The table 6 is mounted upon ball bearings and arranged so that the incline from front to back can be adjusted by means of wedges 14 under the ends 2 of the supporting timbers, these wedges being controlled by means of the rack 17, pinion 18, and lever 19. A reciprocating motion is given to the table by means of a driving mechanism, as shown at the right-hand end of the figure. In this driving mechanism a shaft C² is provided with two eccentrics E and E', which bear against

two rollers E² and E³. By varying the total throw of these eccentrics, by turning them toward or from one another, the amount of travel of the rollers or bearings E² and E³ may be regulated. These bearings are kept constantly in contact with the eccentrics by means of the spring D², and as they are pressed apart the table is forced back by the lever B² and the rod F². As the eccentric advances the lever is allowed to return and the spring quickly returns the table to its position. In the style shown in the illustration a single riffle 15' is used upon the table, and this is given a curved outline or shape similar to

that which would be assumed by the concentrates in passing down the table. The material to be treated is introduced into the trough 11, which is supported by brackets 10, the pulp being introduced at the upper end of the trough and the water through the pipe 13. The advantage claimed for the use of a single riffle is that where a number of riffles are employed the valuable constituents of the ore in passing over them are agitated to such an extent that the fine or valuable portions, such as float gold, are brought to the surface and floated away while by maintaining them behind a single properly placed riffle they can be saved, though the patent states that there is no objection to using other riffles farther down the table if deemed necessary, the principal claims being for the driving mechanism and the methods of support, operation, etc.

COKING PLANT

Of the Durham Coal & Coke Co., Situated on Lookout Mountain,
Dade and Walker Counties, Georgia.

Written for MINES AND MINERALS, by A. W. Evans, Superintendent Chickamauga Coal & Coke Co.

The mining property of the Durham Coal & Coke Co. is situated in Walker and Dade counties, Georgia, on Lookout Mountain, the Durham coal outcropping on an eminence known as Round Mountain, 1,849 feet above mean tide.

Only a remnant of the coal measures exists in Northwestern Georgia, constituting the plateaus of Lookout and Sand mountains. The coal measures embracing an area of 116 square miles.

Lookout Mountain consists of a plateau encircled by a wall of conglomerates. Above this a higher plateau remains, forming the coal measures. The correlation of the Georgia coals with those of other Southern States is not satisfactory, and the question is involved in a conflict of opinions, yet on first examination the Georgia coal field appears to be a continuation of the Tennessee coal field. The coal field of Georgia has suffered from geological causes, and the agencies of erosion have obliterated a large percentage of the original deposit.

The amount of coal in the Durham seam is a fixed, definite quantity. Above the horizon of conglomerate, five seams of coal occur, but the Durham seam is the only one of any consequence. Its position is 615 feet above the conglomerate, and a chemical analysis by Mr. Theodore F. Jewell, Commander, U. S. Navy, Washington, gives the following result:

Moisture	0.310
Non-combustible volatile matter	1.330
Combustible volatile matter	14.594
Fixed carbon	80.084
Sulphur	0.176
Ash	2.922

General Structure of the Coal Field.—The dip at the mines is less than 1°. At any point in the coal field, where the bedded rocks are exposed, it appears that the rocks lie perfectly horizontal. On the eastern side of Lookout plateau, the strata dip northward, increasing to 12° or more. Northward the strata dip at much greater angles but flatten out toward Lookout point. So also they flatten out southward, in consequence of which the seams in the central portion of the mountain lie at low angles.

The Durham coal is 48 inches thick, with a persistent parting of fireclay ranging in thickness from 6 inches to 36 inches. This coal is of exceptional purity, and its specific gravity is 1.28. The coal is soft and friable, has no distinct cleavages, but inheriting a low percentage of ash and sulphur it is pre-eminently a coking coal.

The mining plant is located on lot 315 in Walker County, and is reached by the Chattanooga & Durham Railroad, 17 miles west of Chickamauga. The eastern terminus of the road is at an elevation of 1,810 feet above mean tide. This road furnishes a splendid means of getting the section of the coal measures. The mine is worked on the pillar-and-room system, entries being driven at convenient distances, usually at right angles to the main haulage entry. Then on each side rectangular rooms are worked out. At present the main No. 1 entry is driven about 5,000 feet.

FIG. 1. HEADFRAME, BIN, AND TRESTLE, DURHAM COAL & COKE CO.

The coal from the three openings is delivered at one central point for tipping and washing. The coal, after leaving the car, passes over bar screens, spaced 2 inches apart, and at an angle of 38°; the fine coal falls into a retention bin, from which point it is carried by suitable machinery to a 400-ton Robinson-Jeffrey coal washer. Here it is freed of slate and other impurities and is then conveyed to a settling bin, from whence it is loaded into railroad cars for the coke plant at Chickamauga.

The coke plant consists of 101 12 ft. × 7 ft. beehive ovens in one continuous battery 716 feet in length. The bank of ovens

is on a 1-per-cent. grade, the coke wharfs are 30 feet wide and 4 feet above coke tracks. The larry track is laid with 56-pound rail, using long spliced joints, track supported by brick piers. The ovens are "staggered." The dimensions of retaining walls are as follows: Width, 32.25 feet; height, 9.25 feet, with a batter of 2.6 inches per vertical foot. The base of the retaining walls is 3.5 feet. The ovens are spaced 13 feet 6 $\frac{1}{2}$ inches on centers, and are perfectly circular. The absence of the long "neck," as in the old style ovens, makes this style of oven desirable, as the cost of repairs is low, the masonry of retaining walls remaining intact no matter what kind of repairs the oven proper is undergoing. For this style and size of oven it requires the following material:

For dome, 100 9-inch skews.
Bottoms, 120 12 in. $\times$ 12 in. $\times$ 3 in. tile.
Door, 12 No. 7 jambs.
Door, 12 No. 8 jambs.
Door, 9 No. 9 arch.
Ring walls, 1,450 No. 1 regular key.
Crown, 2,450 No. 1 C key.
Pillars and footings, 1,000 common hard-burned bricks.
1 eyebolt or charging port ring.
1 $\frac{1}{2}$ tons of fireclay.
Castings, 1,188 pounds.

The door casting in position is "flush" with inside radial lines of ovens, the top resting against cast-iron arch frames 5 feet 10 inches long, supporting arch in masonry of retaining walls above the door. The recess in masonry at oven door is 2 feet 7 inches in width, and flares to 5 $\frac{1}{2}$ feet at front of wall at bottom, and 4 $\frac{1}{2}$ feet at the top, this opening is 6 feet in height.

From the bottom of oven there is an apron of masonry which causes the coke, when drawn, to fall at front of retaining

with 10 in. $\times$ 14 in. cylinders. A loose drum 29 inches in diameter by 30 inches long, mounted on a 3 $\frac{1}{2}$ -inch shaft receives the rope. The engine is geared to drum in the ratio of 4 to 1.

There is a powerful friction clutch on main drum shaft connected by proper levers and convenient to the engineer. This engine was built by the S. Flory Mfg. Co., of Bangor, Pa.

The larry is of the double-discharge type and weighs 6,970

Fig. 3.

pounds. The method of operation is as follows: The larry being at loading terminals, the clutch engages the drum, then steam is admitted to the cylinders and the car moves up the 10-per-cent. grade with its load of 7 tons of coal at the rate of 348 feet per minute. The strain on the rope is 2,365 pounds, and the actual horsepower developed 35 $\frac{1}{2}$. When the car reaches the "knuckle," steam is cut off, the clutch thrown out, and it runs by gravity to oven to be charged, when the brake on car is applied.

After the car is emptied, the attendant signals the engineer by means of electric signals, the clutch is "thrown in" and engages the drum, steam is admitted to cylinders until the larry gets within 25 or 30 feet of knuckle, the speed is accelerated for a short distance, then steam is cut off, clutch thrown out, and the

wall. Montague & Co., of Chattanooga, have all patterns for shaped brick.

The original plant consisted of 50 ovens, and the coal-handling machinery was designed to expedite the charging of 25 ovens per day. After the writer assumed charge of the operating department and had erected 51 additional ovens, it was made manifest that the facilities for charging ovens were wholly inadequate for the service.

The method of charging the ovens was as follows: The washed-coal cars were run out on a spur track on a 2-per-cent. grade gaining sufficient elevation for a retention bin 70 feet long by 18 feet in height, into which the washed coal was delivered. Underneath this bin, and running its entire length, was a 12-inch cast special conveyor which delivered the coal to an elevator with buckets 6 in. $\times$ 8 in. spaced 26 inches apart. This elevator delivered the coal into a small bin above larry track, with proper elevation for larry to receive the coal. From this point the larry would run by gravity. The machinery was actuated by a small upright engine too light for the service.

The approach to ovens, retention bin, and headframe of elevator, with trestle of present arrangement for charging can be seen in Fig. 1.

The present arrangement consists of a trestle, leading from east end of ovens on a 10-per-cent. grade, consuming an angle of 90° by a curve of 40 feet radius, approaching the loading terminal. Deflecting curve sheaves are placed at proper distances apart on this curve. Ten feet west of apex of angle formed by the 10 per-cent. grade of inclined trestle and the 1-per-cent. grade of original larry track trestle, are placed two 30-inch sheaves mounted on 2 $\frac{1}{2}$ -inch shafts, spaced 33 inches on centers. The wire rope of $\frac{1}{2}$ -inch diameter is led from engine, underneath trestle, between these sheaves and attached to larry, as shown in Fig. 2. The larry is operated by a pair of engines

larry by force of its momentum is carried over the "knuckles," the brake on the engine then regulates its speed to the loading terminal. The entire battery is connected to engine room by electric signals. It is possible with this arrangement to charge 100 ovens in 12 hours.

The washed coal when delivered at ovens contains 8 per cent. of moisture. 9,143 pounds of coal is charged for a 48-hour burning, and 14,000 pounds for a 72-hour burning; the latter levels to a height of 22 inches in the oven and it requires 10 minutes to level this charge properly. The coke is "watered out" in the oven by means of a sprinkler, Fig. 3. This sprinkler is so designed that no water can play on the crown of oven. After a series of tests, with respect to oven as designed, I arrived at this result: ash 3 per cent., total coke 63.9 per cent.

Taking the proximate analysis of Durham coal and assuming that the fixed carbon, ash, and 60 per cent. of the sulphur make coke, we get a theoretic coke of 83 per cent.

Analysis of Durham coke, by J. Bladget Britton & Co., Warrenton, Va., is given as follows:

Moisture	0.240
Volatile matter	0.301
Fixed carbon	94.636
Ash	4.823
	100.000
Sulphur (Included in the above)	.651

For sake of comparison I give below the analysis of two other favored cokes.

	Pocahontas Flat Top.	Cornucopia.
Moisture	0.196	0.060
Volatile matter	0.494	0.427
Fixed carbon	93.625	84.962
Sulphur	0.677	0.810
Ash	5.004	9.741

The two chief essential physical requirements of the Durham

coke, hardness of body and well developed cell structure, make it an admirable foundry coke. There is no material difference, other than strength between the 48- and 72-hour coke. The percentage of cell structure, by volume, appears the same in the coke of different burnings.

The water works consist of a Worthington duplex pump—taking water from a well and pumping it through a 4-inch main to a stand pipe 40 feet high by 12 feet in diameter. The pressure at ovens is about 30 pounds.

MINES OF VELARDENA, MEXICO.

A History and Description of Some Little Known but Productive Mines Which Have Been Worked for Centuries.

Written for MINES AND MINERALS, by Ernest E. Payne.

The great lead carbonate mines of Velardena are little known outside of their immediate locality, the company operating them has rather turned the cold shoulder to outsiders, consequently the Velardena Mining & Smelting Co. own or control mostly all the large known veins and deposits in the district. Yet there is some free ground, and were the Velardena district in the United States, it would not be too much to say, that it would be overrun with prospectors.

Location.—Torreon, Mexico, is the junction of the International and Central Railroad. From there the International runs to Durango; in fact, the International is the direct line from Eagle Pass to Durango. Velardena is on the branch between Torreon and Durango. From Torreon, a ride of a few hours over a diversified country, through the fertile valley of the Nazas, takes one into the chaparral-covered deserts; low ridges of limestone rise on either side of the line, with now and then a porphyry cap on small hills, which would suggest probabilities for minerals. Over the big loop, rivaling the famous horseshoe curve in Pennsylvania, we reach the station of Pedricena, from which a branch freight line leads to Velardena, some six miles up the valley.

A mule car is here waiting for such fortunates as are supposed to come for business with the Velardena Company. Some two miles from the station we come to the ranch of Pedricena, where is the district church, where all good Catholics from Velardena and surrounding ranches journey every Sunday morning to mass. As we near Velardena we see that we are in a long narrow valley; on the north side rise the San Lorenzo Mountains, and on the right the small isolated group of mountains called the "Sierra de Santa Maria," where limestone and porphyry are the predominating rocks.

Just before reaching Velardena we pass the "Cerro de Chihuahua," a singular looking mass of porphyry, under which are found scattered, bunches of carbonates. On the other side of this hill we come to shaft No. 5 of the Velardena Mining & Smelting Co.

Along the foot of the Santa Maria lie the deposits, running more or less east and west, and they occur practically all along the foot of the hills, possibly some three miles. Country rock is lime, with occasional bunches of porphyry showing up through the range. A singular fact is that no other mines of any permanency are found in these hills. Occasional peaks are capped with

silicious iron caps, and they have been so far diligently prospected without success.

The Velardena Company operate five shafts on these deposits. Reliable information cannot be obtained as to value of these ores, as the whole concern is under sale to an English syndicate. The values, however, are not high, the abundance of the ore is the factor. The ore occurs in great "salons," as they are called by the Mexicans, twenty to forty feet wide, and of varying length. The deepest workings have penetrated into the sulphides. The mines are worked by a system of pillars, taking out good ore and leaving poor ore as pillars. The water is very heavy. The output of the mines is about 250 tons a day.

The Smelter.—Close by the mines is the smelter, where they are converting 250 tons daily into base bullion, which is shipped and refined in Omaha. They have also a matte smelter in which they are smelting copper ores from a large copper deposit in San Lorenzo, and from which they are turning out a matte containing 50 per cent. copper, smelting approximately 10 tons to 1.

Lime for the smelter is secured close at hand; iron, however, is brought from the celebrated iron mountain in Durango. Silica is secured from their silicious mines in the San Lorenzo, the Terneros mine yielding much silicious ore.

The company has one of the finest installations of machinery in Mexico. The larger part of their engines, pumps, etc., are now run by compressed air, supplied from a central station. The town and smelter are lighted by electricity. Strange to say, this company, with all its surplus power, has never done any prospecting with the diamond drill, preferring the slower and more costly method of shafting to search for ore bodies.

The town contains about 3,000 people. Probably there are seventy-five white employees in the works. The efficient general manager of this concern is Don Carlos Wilhelmi, Don Mateo Dahlgren, the mining superintendent, Don Guillermo Daly, the smelter superintendent.

Wages for miners in this camp range from seventy-five cents to \$1.50 Mexican per eight hour day. Laborers seventy-five cents Mexican. The company runs several stores; men are paid partially in cash and partly in checks on stores.

Mines in San Lorenzo Mountains.—The mines in the San Lorenzo Mountains were opened up by the early Spaniards about the same time as the Avino district and Pachuca district, somewhere between 1650 and 1700. The Terneros, Chona, Coronillos, Quartos, Roca, and Hileta mines were all opened about the same time. The Roca mine was abandoned by the Spanish at the time of the war of Independence, and it lay idle until it was acquired by Francisco Rao Patra, a Mexican who came into this district about twenty-five years ago, and established a native smelter at Carlena, where he smelted ores brought him by "busconies" or prospectors. When his smelter was purchased by the new Velardena Company to prevent him running his plant on ore stolen from their mines, he turned his attention to mining, and acquired by denouncement, the Los Bancos, Santa Juana, Negrita, and Roca mines, and did a little work on them all in the Mexican fashion, working out little bunches of ore and throwing waste behind him, he soon found himself faced with a problem of cleaning out his mines or abandoning them. About this time he sold the Santa Juana, Los Bancos, and Negrita to J. Ernest Mining Co., the Hileta to William Godfrey, and later the Roca to Mr. Charles Von] Brandis, the present owner, all of whom

ROCA SHAFT AND WORKS, SAN LORENZO MOUNTAINS.

started systematic work on their mines, with the result that today these mines are paying handsomely. Within two years of the purchase of the Roca, the little mine had paid for itself, and with depth its ore values have increased in richness.

The Roca mine is developed by a vertical shaft 350 feet deep with levels at 130 feet, 202 feet, 260 feet, and 320 feet. Levels are all about 120 meters in length, connected every thirty meters by winzes. Sinking is carried on all the time and ore reserves are always kept two years ahead. The ore is a sulphide, averaging by carload lots, 200 ounces silver, 15 grams gold, 15 per cent. lead, 3 per cent. copper, excess silica, zinc, and some lime.

Strange to say, zincblende (sphalerite) carries high silver values. The prevailing ore, however, is tetrahedrite. The vein averages 4½ inches wide and is a true fissure vein running N. E. and S. W., cutting through diorite and garnet rock. The heaviest mineralization is on the walls of the fissure, the vein carrying in the center a thin ribbon of silicious gangue showing how the minerals had crystalized out of the heated waters which had filled the fissure.

The Roca is surrounded by producing mines of the Velardena company and the J. Ernest Company. To the south may be seen the old open cut on the Chona, Coronillos and Ternereros from which twenty-two millions were taken by the old "conquestores." Further south is the little Hileta, a gold producer, to the south of that the old San Mateo, and the Ternereros, now developed by tunnel, thoroughly equipped with air drills and compressors, and which is now producing 100 tons of silicious ore daily of an average value per ton of \$50 Mexican.

Parallel to the Roca runs another small vein, called the Negrita, which is just being opened up. It is in the same location as the Roca. The ore was struck at 150 feet about four inches wide, a very silicious ore carrying copper in form of chrysocolla, value 700 oz. per ton silver, 16 per cent. copper, 8 grains gold. This prospecting shaft is on the west end of the Roca claim and shows a peculiar condition of limestone, which has had the lime partly replaced by silica.

The Roca and Negrita mines are equipped with two-horse common-sense whims, as are most all the mountain mines. The mines in San Lorenzo are all dry. Coal is expensive and water costs about two and one-half cents per gallon delivered at the mines.

During the six years that the Roca has been under the ownership of Mr. Von Brandis, it has produced over \$300,000 Mexican.

LEGAL DECISIONS ON MINING QUESTIONS.

Evidence in Action to Quiet Title.—Where plaintiff in an action to quiet title to mineral land claimed exclusive adverse possession from the date of his location, and the evidence showed that defendant had purchased an interest from prior locators, and had continued in possession with them until they leased it to a third party for a term of years, which expired after plaintiff's entry, the lease was competent evidence to show that defendant was in possession by his lessee when plaintiff was claiming exclusive possession. — *Simmons v. McCarthy*, 60 Pac. Rep. (Cal.) 1037.

Mining Claim Located Across the Vein.—Under the rule that where a lode mining claim is located across, instead of along, the vein, the original side lines become end lines, and the end lines side lines, the owner is entitled to all the rights with reference to the new side lines that he would have had if they had originally been located as such, including the right to follow the dip of a vein having its apex within the surface boundaries of his claim beyond the vertical plane passing through such lines. — *Empire Milling & Mining Co. v. Tombstone Mill & Mining Co.*, 100 Fed. Rep. (U. S.) 910.

Foreign Corporation.—A single contract made by a corporation owning mining ground in a territory, by which it employs and agrees to pay a second party to exploit and develop the property, does not constitute a carrying on of business in the territory by the corporation, within the meaning of a statute requiring foreign corporations carrying on business within the territory to file copies of their articles of incorporation, and providing that every act done by them prior to the filing thereof shall be void; and such statute does not effect the validity of the contract. — *Empire Milling & Mining Co. v. Tombstone Mill & Mining Co.*, 100 Fed. Rep. (U. S.) 910.

Optional Contract.—The owner of land granted to another the oil, gas, and other minerals underlying the land, on condition that the grantor should have a certain share of the oil, gas, and minerals so mined. The grant provided that, if no well was completed by the grantee within 90 days from and after the date of the grant, the same should be null and void, unless the grantee should pay the grantor a certain rental for each year the completion of the well was delayed. It was further stipulated that

the grantee should have the privilege of surrendering the lease at any time by paying the rental on the land to the time of surrender. *Held*, since it was optional with the grantee as to whether or not anything should ever be done by him, and as no well was made, there was no obligation to pay any rent, or to make compensation for oil or gas. — *Brooks v. Kunkle et al.*, 57 N. E. Rep. (Ind.) 260.

Contributory Negligence Not a Defense.—When an employee of a mine, endeavoring to alight from the cage at the surface opening of a shaft, fell into the shaft and was killed, the opening of the shaft being enveloped in darkness by reason of no sufficient light being furnished, as required by Hurd's Rev. St. 1889, c. 93, § 6, contributory negligence of deceased could be no defence to the mine owner in an action for damages for deceased's death, under chapter 93, § 14, providing that any injury from failure to comply with the provisions of the act shall give a cause of action. — *Odin Coal Co. v. Denman*, 57 N. E. Rep. (Ill.) 192.

When Accounts Began to Run.—Where plaintiff sold mining supplies to defendant from time to time, and monthly bills were rendered therefor, and interest charged thereon, with the understanding that defendant was to be carried till he could make payment by shipping ore, such purchase did not constitute a continuing running account, but each was made under a separate contract, payment for which was due at the end of the month, from which time the 90 days required by Code Civ. Proc. § 2131, for filing of a statement of lien began to run. — *A. M. Holler Hardware Co. v. Ontario Min. Co. et al.*, 61 Pac. Rep. (Mont.) 3.

Option to Purchase.—A contract by plaintiff to sell, and by defendant's predecessors in interest to buy, certain mining property, which contract is personal, and does not, in terms, run to heirs and assigns, and under which the prospective grantees, although given possession, could neither sell nor assign, without grantor's consent, until they had become entitled to a deed by performance of certain conditions, one of which was to pay grantor a certain sum out of the property, is a mere option to purchase, with a license to extract ore, and not a covenant running with the land. — *Smith v. Jones et al.*, 60 Pac. Rep. (Utah.) 1104.

Additional Certificate of Location.—Gen. St. § 2400, allows the filing of an additional certificate of the location of a mining claim where the locator apprehends that his original certificate is defective, or he desires to change his surface boundaries, or take in part of an abandoned claim. *Held*, that where an original certificate sufficiently located a discovery shaft, and an additional certificate gave a description by metes and bounds starting with the discovery shaft, and running to posts in a mound of stone, the claim could be identified with certainty from both certificates taken together, and hence such certificates were admissible to establish the locator's claim, though neither taken alone, sufficiently described such claim. — *Duncan v. Fulton et al.*, 61 Pac. Rep. (Col.) 244.

Working Property of Another.—Defendant, the owner of a mine, contracted with plaintiff, which owned an adjoining claim, to extend its workings into such claim, for a stipulated price, for the purpose of exploiting and developing the property, and agreed that, should any marketable ore be taken therefrom in the course of such development, it would sell the same, and account to plaintiff for the proceeds. *Held*, that defendant was not stopped by such contract from claiming the proceeds of ore so removed and sold as its own, where, in making the development, it discovered that the vein from which it took such ore had its apex within the lines of its own claim, and the ore was, therefore, its own property. — *Empire Milling & Mining Co. v. Tombstone Mill & Mining Co.*, 100 Fed. Rep. (U. S.) 910.

Was Tipple House the Top of the Shaft.—Hurd's Rev. St. 1889, c. 93, § 6, provides that a sufficient light shall be furnished at the top of every shaft of a mine to insure the safety of persons getting on or off the cage; and section 8 requires that the top of every shaft shall be securely fenced by gates properly protecting such shaft; and section 14 provides that any injury arising from failure to comply with the provisions of the act shall give a cause of action. *Held*, that where a mine owner had erected above the opening of a shaft an uninclosed framework of timber, supporting a structure called a "tipple house," to which the cage could be hoisted, and through which the day shift entered and left the shaft, but it was customary to let off the night shift at the surface of the ground, and plaintiff's intestate being one of the night shift, and endeavoring to alight, fell into the shaft and was killed (it being dark at the surface, and their being no fence there), it was proper to submit to the jury the questions whether the surface or the tipple house was the top of the shaft, within the meaning of section 8, whether the proximate cause of the injury was the absence of a light. — *Odin Coal Co. v. Denman*, 57 N. E. Rep. (Ill.) 192.

ACCIDENTS IN COAL MINES.

Comparison Between the Coal Production and Number of Accidents and Their Causes in Different States and Countries.

By Thomas K. Adams, Mine Inspector.*

Accidents in coal mines is a subject demanding our thoughtful and most serious consideration; in fact, it is a problem which merits the putting forth of the best efforts of every member of this society for its solution. Some of the important phases of this question have been discussed in some of the former meetings of this Institute; many able papers have been written by expert and practical men upon it, and State Mine Inspectors have treated very voluminously in their official reports, on this topic; therefore, in view of these facts, little that is new can be added by us to the information you already possess relative thereto. However, if we can do nothing better we can repeat the same old story, and by its repetition we, with the others, hope to so impress its teaching upon the minds of all persons employed in and about the mines that they will instinctively obey its well intended admonitions.

The life of any man (unless he be a tramp or a criminal) is worth saving. It is vastly more valuable than coal stocks, common or preferred, or any other earthly treasure; hence, nothing should stand in the way which would militate against its preservation. Not even the greed or selfishness of some men nor the imbecility, ignorance, foolishness, and thoughtlessness of others should be tolerated to act as a hindrance in the saving of human life. The premature death of any industrial worker is always sure to bring adverse and depressive social conditions, especially upon those who are his dependents, likewise upon the community where the accident happened, as well as being a direct loss to the State.

Those calamitous disasters which startle us so frequently, sweeping away, instantaneously, valuable lives by the tens and even by the hundreds, are having a dreadful effect, and in fact the finer sensibilities of the public generally have become shocked or almost paralyzed at their frequency, while those who have been in any way culpable for the sad events have become conscience stricken. During such distressing events we have, as usual, a plenteous crop of apologists and general utility men who appear upon the surface at such times as numerously as the 17-year locusts, bringing panacean healing for all our ills. Those men are very resourceful in offering all kinds of excuses for those who are possibly responsible for such calamities. They will tell us about the subtle agencies in operation in nature's storehouse, the mysteries which wiser men than Solomon cannot unravel, and that those mine explosions are the unavoidable and natural accompaniments which gives harmony to the coal-mining industry. Such rot has no weight with intelligent mining men, of course, but dupes there be everywhere. However much these alarming mine explosions may shock the people generally and cause distress in so many homes simultaneously, yet the blighting social effects caused by such incidents sink into insignificance when we compare the number of deaths resulting therefrom, with the number of fatalities resulting from other causes which happen one by one and in such a manner as to escape public notice or compassion.

We may be pardoned for digressing somewhat from our theme in order to give you an idea of the wonderful advancement which has been attained in the bituminous coal-mining industry of this State. We do this merely for the purpose of showing the progress made along certain lines in the mining of coal, and which has not been secured in others. In the last twenty years we have made marvelous progress in material development. In the year 1880 the coal production in the bituminous mines of Pennsylvania was 17,169,448 tons, with 32,694 persons employed in and about the mines, and the production power per employe in coal during that year was 525 tons; while in the year 1899 there were produced 72,866,943 tons of coal and 91,442 persons were employed, and each person having a production power of 797 tons of coal, which shows an increase in tonnage of 400 per cent., in number of persons employed of 300 per cent., and in production power per employe of 52 per cent. Also in the sanitary arrangements and conditions of the mines we are pleased to state that a corresponding progress has taken place, but we are sorry to state that no apparent betterment in the saving of life has as yet been secured.

In the last 20 years in the bituminous coal mines of Pennsylvania, there were 2,509 persons killed, and the amount of coal produced from the said mines for the same period was 967,777,435 tons, or one death to every 385,698 tons of coal produced. The following classification of accidents for the last 10 years in the

mines of the bituminous regions is here given. We find for this period 1,709 persons lost their lives resulting from four general causes, namely:

Causes.	No. of Deaths.	Percentages.
Falls of coal, slate, roof rock, and sides.....	1,082	63.32
Explosion of gas, etc.	213	12.46
Mine cars	258	14.8
Miscellaneous	161	9.42
Totals	1,709	100.00

There were 3,871 persons injured in the bituminous mines of Pennsylvania during the last 10 years. These non-fatal accidents are classified as follows:

Causes.	No. of Injured Persons.	Percentages.
Falls of coal, slate, roof rock, and sides.....	2,229	57.58
Explosions of gas, etc.	131	3.38
Mine cars	975	25.16
Miscellaneous	536	13.88
Totals	3,871	100.00

These statistics show that the number of deaths and injured persons resulting from mine explosions, etc. is very small when compared with the aggregate number of lives lost and persons injured. The average age of the persons killed, taking the number of lives (462) lost in the years 1890, 1895, and 1899 as a basis with which to obtain the average, is about 32½ years.

We desire now to give some comparative statistics, so as to measure ourselves, relative to the saving of life, by the standards attained along the same line in some of our sister States and in Great Britain. In Great Britain, in 1889, one life was lost for every 178,227 tons of coal produced and for every 530 persons employed, and the average tonnage per fatality for the three years 1896, 1897, and 1898 was 207,605, and the average number of persons employed for the two years, 1896 and 1897, per death was 705.5, thus showing a decrease in the number of deaths, when compared with the coal production and number of employees employed for these two periods, of 16.5 per cent. in the former and 32.5 per cent. in the latter.

Illinois.—In 1889 the number of tons of coal produced per life lost was 333,745, and the number of employees employed per death was 716. The average coal tonnage for the years 1896, 1897, and 1898 per fatality was 265,290, and the average number of employees for the said period was 446, showing an increase in the former of 20 per cent., and in the latter 37.6 per cent.

Ohio.—In 1889 there were 330,527 tons of coal produced per life lost, and 615 persons employed. The average number of tons of coal produced per fatal accident for the years 1896, 1897, and 1898 was 298,875, and the average number of persons employed per death for these years was 659, thus showing an increase in the former of 9.5 and a decrease in the latter of 7.1 per cent.

West Virginia.—The tons of coal produced per life lost in 1890 was 206,358, and the number of persons employed per death was 327. The average tonnage per fatal accident for the years 1896 and 1897 was 207,366, and the average number of persons employed for the same years was 359, showing a decrease in the former of ½ per cent., and in the latter 9.8 per cent.

Pennsylvania.—The tons of coal produced per death in the year 1889 was 329,766, and the number of persons employed per life lost 529.5. The average tonnage per death for the years 1896, 1897, and 1898 was 323,760, and the average number of employees for the same period was 490.7, showing an increase in the former of 1.8 per cent., and in the latter, for the same period, of 7.3 per cent.

For the sake of easy reference the above results are repeated in tabular form.

State or Country.	Production per Life Lost in 1889.	Production per Life Lost During 1896-97-98.	Increase or Decrease Per Cent.	Number of Employees per Life Lost. 1889.	Number of Employees per Life Lost. 1896-97-98.	Increase or Decrease Per Cent.
Illinois	333,745	265,290	+20	716	446	+27.6
Ohio	330,527	298,875	+9.5	615	659	-7.1
West Virginia ..	206,358*	207,366†	-.5	327*	359†	-9.8
Pennsylvania ..	329,766	323,760	+1.8	529	490	+7.3
Great Britain ..	178,227	207,605	-16.5	530	705†	-32.5

* Read before the Western Pennsylvania Central Mining Institute, June 29, 1900.

* For 1890. † For 1896 and 1897.

Comparative Results.—Pennsylvania shows a betterment over Great Britain in tonnage per death of 55.8 per cent., over Illinois of 22.2 per cent., over Ohio of 8.3 per cent., and over West Virginia of 59 per cent.; but with the number of employes Great Britain shows a betterment over Pennsylvania of 43.6 per cent. Ohio is better than Pennsylvania 34.2 per cent. Illinois is worse than Pennsylvania in this respect by 9.6 per cent., and West Virginia is worse by 36.6 per cent. But if we compare the statistics of Ohio with those for the mines in the Third, Fourth, Sixth, Eighth, and Tenth bituminous districts of Pennsylvania, where almost similar conditions prevail in the mines of these two places, we find the following comparison for the years 1896, 1897, and 1898: The average tonnage for these years in Pennsylvania was 436,843 per life lost, thus showing a betterment in Pennsylvania's favor over Ohio of 61.5 per cent. in tonnage, and in persons employed of 25.2 per cent.

From the annual report of the chief of the Bureau of Mines of Pennsylvania for the year 1898, the number of deaths by nationalities (which we change to percentages) is given as follows: Americans, 25.63 per cent.; English, 12.56 per cent.; Germans, 4.52 per cent.; Irish, 4.52 per cent.; Scotch, 3.52 per cent.; Swede, 5.3 per cent.; Welsh, 1 per cent.; Austrians, 6.7 per cent.; Hungarians, 5.52 per cent.; Italians, 8.3 per cent.; Polish, 8.54 per cent.; Russians, 1 per cent.; Slavish, 14.6 per cent. Classifying Americans, English, Irish, Scotch, Germans, Swedes, and Welsh as English-speaking people, or who understand the English language, their percentage of fatalities is 56.78 per cent., and the Austrians, Hungarians, Italians, Polish, Russians, and Slavish as the non-English-speaking people, they represent 43.22 per cent. of the total fatal accidents. The ratio which the English-speaking people bear to the non-English-speaking people of the total number of employes employed in the bituminous regions of Pennsylvania we have no accurate statistics at hand to determine.

In the same Pennsylvania Bureau report it is stated that 41 per cent. of all the fatal accidents, and 43 per cent. of all the non-fatal casualties, are attributed to carelessness or violations of the mining laws by the victims themselves.

Now, what do these statistics reveal? They certainly show no reduction in the number of fatal accidents during the last 20 years. Then this pertinent question arises: has a point been reached in the mining of coal when no improvement can be had in the saving of life? To affirm this proposition would be a reproach upon every intelligent mining man of this State. We have not reached our ideal along this line by any means. We are decidedly of the opinion that there is an excessive sacrifice of human life going on in the mines of this Commonwealth; hence, the causes leading thereto must be discovered, responsibilities fixed, and the remedies must be vigorously and effectively applied. We are thoroughly convinced that at least 50 per cent. of all the accidents in the mines can be avoided if the people (mine operators, mine officials, and miners) connected with the mining operations so will it.

We are told that the reasons why progress in the saving of life is not apparent is because there have arisen new and more dangerous causes in the mines during the last 10 or 20 years which were not present prior to that time, such as: the mines are more extensive in old abandoned and live workings, with all their attendant evils; coal is taken from greater depths and from greater distances under the hills, thereby liberating more explosive gas into the mines than formerly; 902 mining machines are now in use with their power to produce dust and noise, and bringing a train of other adverse conditions into the mines; haulage machinery running trains of coal at high speed; electricity at 250 to 400 volts conducted through bare wires dangling about the ears of employes on haulage roads and travelingway claiming its victims; motors of all kinds doing work, adding dangers and confusion in the mines, which were not present 20 years ago; men have been introduced into the mines by the hundreds and thousands for the purpose of mining coal who are nearly as ignorant about mining methods, and the putting into practice the proper safeguards for the protection of their own lives, as the animals that haul the coal from them, and discipline has become so lax that nearly every workman has so imbibed the spirit of liberty that he has become a law unto himself. These things are the outgrowth of the spirit of the times.

What are the essential remedies to be applied to cope with the present condition of things? We would suggest the following: First, to prevent mine explosions we must remove the causes. This can be done by having strong currents of air traversing all the live and abandoned workings of the mines, where practicable, by the method of divisional ventilation. Accumulations of gas in waste workings must be removed or prevented by the methods of boring holes to them where they would be of practical utility. All portions of the mines to be constantly under the supervision or oversight and inspection of firebosses, with properly arranged divisions of not larger extent than can be conveniently inspected

frequently during the daytime as well as in the morning; as now required by law. Dust must be removed from the mine or thoroughly dampened in the immediate vicinity of shot firing. The firing of shots where gas is being produced, or where dust may be present, should be done by careful and competent miners, or done under the oversight of prudent and practical men. Also flameless explosives should be used. Men should not be put into the mines where firedamp exists, nor safety lamps put into their hands, unless they are competent to use them properly and understandingly, and are capable of receiving instructions from the person having the oversight of the division of the workings where they labor. Both the spirit and the letter of the present law, regulating this matter, should be rigidly obeyed. Firedamp and coal dust are not the miner's most dangerous foe, for only 12.46 per cent. of all the fatal accidents result from explosions, and in the mines where prudent, conscientious, and thoughtful men are in control of them, together with a liberal but not wasteful expenditure of money to put into force all necessary safeguards, mine explosions will be few indeed, if not entirely eliminated.

Sixty-three and thirty-two hundredths (63.32) per cent. of all the fatal accidents in the mines are due to falls of coal, slate, roof rock, and sides. We are decidedly of the opinion that the securing of the roof, slate, etc., should be done by specialists, or men employed specially for such a purpose. Very few miners are expert timber men, and when they do set posts they are seldom set properly, and they are put up without the apparent exercise of good judgment. They do this kind of work in a haphazard manner, and the time given to securing their working places is given grudgingly, and such work is usually put off to a more convenient season. There should be one man employed to timber, or at least have the work done under his supervision, so many rooms, according to the nature of the roof and the amount of timber to be used. This man should have a general oversight of all the working places in his division, and be held responsible for their safety. He should see that each miner is supplied with the requisite amount of timber.

Mine cars are another fruitful source of accidents, and 14.8 per cent. of them are due to this cause. Mine cars should be carefully inspected (in the same manner as railroad cars are inspected), and if found defective they should not be allowed in the mines until they are repaired. Haulage-road beds should be kept free from water, a good weight of T iron rails and plenty of good ties should be provided and all kept in a solid condition. Brakes should be used on all cars instead of spragging the wheels, and all trips of cars be kept under perfect control. Drivers should ride on rear end of trips instead of the front end or between the cars, and all haulage roads should be of ample size and kept clean. Dilly trips, or trips by any other method of haulage when men are required to ride upon them, should not be run at a higher rate of speed than about five miles per hour. The rope rider or motor driver should have exclusive control of the running of all trips of cars, and should he know of any unauthorized person being on them, he should immediately stop them and put him off and report the same to the proper authorities. There are 9.42 per cent. of the accidents due to miscellaneous causes, such as electric wires, mining machines, and machinery in general, careless handling of explosives, premature blasts, men falling down shafts, caught under hoisting cages, by mules, etc. No electric wires should be allowed on any travelingway where a high voltage is required, neither should any electric motor be allowed where men are required to travel, and in the workings where firedamp is being produced, electricity in any form should be prohibited. If electric wires should be used they should be conducted through separate passageways provided exclusively for their use, and when they have to cross over haulage roads a groove of sufficient depth should be cut in the roof and the wires properly cased with insulating material. Nearly all the other causes under this head are well provided against by the mining laws, except mining machines.

Mining machines are claimed to have added considerably to the death rate at many of the mines, and owing to this idea prevailing among so many men their exclusion from the mines has been advocated. The remedy, in our opinion, does not lie in this direction, but limitations should be put upon the use of certain types of machines under certain conditions. If the mine roof or slate will not admit of the use of machines with safety, they ought to be excluded from such mines; but we are convinced (except in some very exceptional cases) that all types of machines can be used with a reasonable degree of safety where firedamp is not present. In order to accomplish this, however, a very radical change in methods must be effected. The very harmful parsimony so evident under present methods of operation must be eliminated. More time must be allowed to do the work and a safer system of timbering must be adopted, which can be done both safely and economically.

Another of the great causes in maintaining the high death rate in the bituminous mines of Pennsylvania is the employing of so many men to mine coal who are utterly incapable either by intelligence, experience, or training to protect themselves against the danger incident to mining. Too many of the non-English-speaking people are like sheep led to the slaughter. They are so ignorant of mining methods and the dangers incident thereto and of the use of the necessary safeguards for the protection of their lives that the great wonder to us is that more of them are not killed. They are employed by the hundreds to go into the mines to labor at all kinds of work without question, by those who employ them, as to their previous service in the mines or their ability to take reasonable care of their lives. A large number of such people know practically nothing about the proper use of the safety lamp and much less about firedamp and its dangers. They practically know nothing about how, where, and when to use timbers in their working places. Even their attention is not called to the mine rules, and all lawful requirements are like a sealed book to them. Owing to the mine foreman's inability to converse with this class of laborers in their own language, they cannot have the benefit of his instruction when he makes his visit to their working places for that special purpose. Under such conditions those people should not be employed in such large numbers, and when employed, their employers should be held responsible for their safety. When employed they should only work when under the constant supervision of some competent or trustworthy person until, at least, they are instructed in the proper use of known safeguards and in the methods used in detecting dangers. This suggestion will apply with equal force when Americans are employed to mine coal when they have had no previous experience. The Americans have the highest death rate when the percentages are considered by nationalities, hence the necessity of putting some restraint upon inexperienced men being allowed to work in the mines until they have received proper instructions, etc.

Still another of the supreme causes for the failure to reduce the number of accidents is the utter lack of discipline among the employes in so many of the mines. It seems that the underground mine officials, with, of course, a few honorable exceptions, have evidently no control over the men who are supposed to be under their authority. Everything appears to be running at loose ends. The mine officials must exercise their authority and maintain discipline among the employes at all hazards. When a reasonable order is given by any official it must be enforced by him and implicitly obeyed to whomsoever it is given. Men must be made to respect the law, and all mine operators and officials must set the example by willingly complying with all of its requirements. Mine foremen must not for a moment allow themselves to be intimidated by superiors or inferiors in station, by means used directly or indirectly, in seeing that the letter and even the spirit of the mining laws are faithfully carried into effect, and all lawful duties required of them must be conscientiously performed and done willingly, methodically, and without laxity. Mining laws are enacted for the protection of the workingmen, and any infraction of them by any persons should be visited by a penalty upon the guilty parties. Leniency shown to some men breeds contempt in them for law, hence the violators of it must be punished both speedily and with certainty. If our present machinery to be put into motion in order to have the mining laws enforced is too complex, it must be simplified to meet the demands, and nothing that is reasonable should be left undone that will assist us in reaching our ideal in the saving of human life.

Dawson and the Yukon Territory.

The census of the Yukon Territory, taken last April, shows an increase in the population of Dawson City of nearly one thousand since September, 1899. The population of the whole Yukon district, however, has decreased some two thousand.

There is an ample supply of good water now, pumped from artesian wells and piped to stores and houses at a cost to the buyer of from \$4 to \$5 per month; large restaurants and saloons are charged \$10 to \$15, and hotels \$25.

The town is busy as is usual at this season of the year, and money is plentiful. There is not the disposition prevalent in former years to squander hard-earned money, but the temptations remain the same. There are no places for the miners to go to for innocent recreation, so they naturally flock to the gambling halls, which are made inviting enough. Gambling is not looked upon in this community as a crime, but as a pastime, and it is no uncommon sight to see employer and employee at the same table; lawyers and their clients, bankers, and bank clerks all patronize the tables, and it was only lately that the head of a large trading company lost \$21,000 in a single night. A conservative estimate as to the output of gold for this season, as published in a Dawson newspaper, places the figure at \$18,000,000. There are 5,280 men employed at an average wage of \$1 per hour.—*U.S. Consular Reports.*

THE HAILE GOLD MINES

Of South Carolina.—Some Striking Peculiarities in Regard to the Ore Bodies as Compared with Most Western Deposits.

Written for MINES AND MINERALS, by Prof. Arthur Lakes.

In different mining regions we often find very different conditions, both in the character and deposition of ore deposits as well as in the mode of developing them.

No mining region is a hard and fast type or rule for another, nor can any hard and fast rules be laid down for development in different regions. We may have certain general rules laid down in books, but commonly we have to modify and adapt these rules, as well as ourselves, to the circumstances in which we are placed.

Take Colorado; there is a difference in modes of development between the various camps, often but a few miles apart. The fissure veins of Boulder, Clear Creek, and Gilpin counties are developed mostly according to a regular type system of shafts, drifts, and overhead stoping. At Leadville the great chambers of ore deposits require a different system and the use of square sets. Silver Cliff has great open quarries, and deep open cuts like railroad cuts in its ore deposits. Cripple Creek, too, has its variations from the usual rule, as, for instance, in the circular funnel or well-like deposit of the Anna Lee.

When we leave the West and go South to the Southern States, such as Georgia and South Carolina, we find an entirely different condition of ore deposits, and, in consequence, a very different method of development. Here the characteristic feature is that of broad zones, it may be some hundreds of feet in width, composed of narrow lenses and veinlets of low-grade ore disseminated through a zone of schistose or slaty country rock. Such deposits have to be worked wholesale to be worked at profit, consequently,

CROSS AND HAILE PIT.

instead of the regular orthodox shaft and narrow tunnels and drifts, we find huge, open, crater-like pits 200 feet wide, it may be, by a hundred or more feet deep. In the drifts and shafts communicating with these, we find ourselves in vast, open, cave-like chambers from which the great low-grade bodies of ore have been taken, and we look up uneasily into their dark recesses, wondering how the roof keeps up, seeing there is not a stick of timber to support it, for none has so far been found necessary. We observe that the mine is supported mainly by natural pillars, as in a great coal mine; such are the striking features of the celebrated Haile mines we lately visited in South Carolina.

The general geology of this region is as follows: A country composed mainly of clay slates, or alumina-magnesian slates, or perhaps more accurately "siliceous-hydromuscovite and argillaceous slates and schists," having a general strike of from 45° north to 70° east and dipping northwest at an angle of from 55° to 85°. These slates are sometimes graphitic and chloritic; they are intercalated with small lenticular quartz veins, and at times with large quartz veins from 12 to 20 feet wide. The large veins are often barren; the values lie in the small quartz veins and schists, both of which are apt to be impregnated with pyritic gold-bearing ore and with free gold. The general masses constituting the ore bodies are lenticular in shape. The outline of these masses does not conform necessarily with the strike and dip of the slates, but is determined rather by the degree of impregnation. The lenses may be 200 feet in length and 100 feet wide; dipping 50° to 60° northeast, or northwest from 45° to vertical.

The whole series is traversed by diabase dikes, having a general north and south course. These dikes are from 12 to 500 feet in width. In the Haile region there are four notable dikes. One is 500 feet wide, which seems to traverse the entire State. Another, 1,000 feet north of this, is 130 feet wide, and a third, 400 feet from the last, is 12 feet at the surface, and below ground increases to 35 feet. A fourth, 500 feet from this, is 150 feet wide,

and about eight miles north is another group of dikes at the Hegler mines.

The heat of the dikes metamorphosed the slates for 400 feet between dikes, and to a considerable distance on either side. The metamorphic influences are shown in a quartzose condition of the slates; chlorite and graphite occur near the ore bodies. Where these dikes have crossed the ore bodies they have enriched the ore. The ore bodies are evidently connected with the dikes, as they are found on both sides of them as "contact deposits," the dike itself being barren of ore. The ore bodies appear to be zones of alteration and substitution of the slates by quartz and pyritic matter. Thus are formed large deposits having a well defined hanging and foot wall, but liable to fade out with depth and length into barren slate. These bodies are, in the Haile property, from 50 to 90 feet in width, with a length of 200 to 600 feet. The depth is from 180 feet at the shallowest to the deepest, which shows ore bodies to continue down below the lowest depth attained, viz., 350 feet. These ore bodies are found both sides of the dike, their length corresponding very well with their depth. The slates of medium hardness are generally the richest; graphitic lamina are good indications of ore; seams of hornstone sometimes occur. Free gold and sulphurets are mingled. Free gold is found at times deposited on graphite and chlorite, and the best ore shows where the ore is most graphitic, quartzose, and chloritic.

The most values derived from the mine are from pyrite, which is very fine-grained and generally disseminated. It is a bisulphide of iron of a greenish tint. Ore containing coarse sulphurets is generally poor grade. The crucial test of the values of the ore is in the amount of free gold it contains, which is in direct proportion to that contained in the sulphurets, and is determined by daily panning. The ore at present delivered to the mill averages about \$4 per ton, of which value about one-third is free gold. The percentage of sulphurets in the ore varies from 2 to 25 per cent.

History.—The first records of any mining being done are in 1829, when the ore was worked as a sulphur and copperas proposition. In 1832, gold mining and working of placers was conducted on a small scale on the branches of the creek, and remains of old arrastras are found. This placer mining, as is commonly the case, led up to the discovery of the ore in place, or what is now known as the Haile mine. At that time the ore on the mine site was divided up into 50-foot-square claims. There was a broad outcropping of oxidized ore on the surface, in other places a broad zone of sulphurets. This was in old slave days. The zones were worked down in big open pits direct from the surface, as may be seen at the Bumalo pit, with one shaft in that case down 120 feet. The ore from the mine was taken by slaves three miles to numerous arrastras. The first mill was of 5 stamps, followed later by 10 stamps, and in 1881 enlarged to 20 stamps.

About 1884 a Blake dry crushing mill of 225 tons was erected in connection with 20 Embrey tables. This was soon abandoned. From being a dry crusher it failed through loss of time and repairs involved; and ran in consequence only one-third of its proper time.

To treat concentrates by amalgamation and roasting, a Walker furnace was established; this also proved a failure. Experiments were carried on without much success from '84 to '88, till Mr. Thies took hold, who recognized it at once as a low-grade, but large-quantity, property, that could be made to pay by judicious development and a suitable milling process.

Prior to his time the company had erected a 20-stamp mill, saving only the free gold and allowing the sulphurets to go down the creek. Mr. Thies put in eight concentrators behind the 20 stamps. This was followed immediately by a chlorination plant for treatment of sulphides with roasting furnace, and three barrels added gradually.

In 1889, the Blake mill was changed to a 60-stamp back-to-back mill with 20 concentrators. Meanwhile the development work of the mine was pushed, consisting of driving drifts and crosscuts from the old shafts to ascertain the extent of the ore bodies. These being found to be very large and of low grade, there followed the question of putting through large quantities of ore to make it a paying proposition. From drifts upraises were made from one level to another, preparing ground for extracting the ore by stoping. Then they tore out the old Blake crusher, preparatory to erecting 40 more stamps, making the present 60-stamp mill.

All work was open cutting until 1880, when underground mining was begun and continued to the present. Although visible coarse gold is now of rare occurrence, the mine has yielded some nuggets worth from \$300 to \$500 from the decomposed slates in the shallow open cuts.

The mines worked at present are the Cross, which is a continuation of the old Haile and Flint pits, and the Beguelin. Red Hill, and Chase Hill pits were not worked for some time, although at the first there was considerable underground work. Work at

the Cross mine was stopped in 1888, and attention concentrated on the Beguelin. The old workings consist of open pits and three perpendicular shafts; one 70 feet deep in ore, one 54 feet deep in the diabase dike, and one 70 feet deep in the foot-wall slates on the southwest side of the dike. The first of these was transformed from a depth of 60 feet downward into an inclined shaft, and sunk in the ore body 195 feet. This shaft was rigged with self-dumping skip crusher, and ore bin, situated over the railroad tracks, which had been extended to the mine. At 60 feet a drift was run north-east until the diabase dike was reached. Meanwhile sinking was continued on the shaft to 120 feet. From this level, drifts were run and connections made with the 60-foot level, which prepared the ground between them for stoping. At 180 feet a similar drift was run to the dike, and connections made with the upper levels in such a manner that the ore from the 60-foot level would fall to the 180-foot level and from there be hoisted to the surface. At 180 feet a drift was started southwest, encountering at 64 feet a dike 125 feet thick, through which the drift was continued to a distance of 600 feet from the shaft. At a depth of 70 feet a similar drift was run and the ore body beyond the dike prepared for stoping by connecting these two drifts by several raises.

Northeast of the shaft a large body was still standing above the 60-foot level. To extract this ore it became necessary to open the mine from the surface and the open pit was started. The ground was stripped to a depth of 15 feet, and from that point the ore was used in the mill. A diabase dike parallel to the schistosity of the country was encountered in crosscutting. On cutting through it a distance of 4 feet it was found to merely divide the ore body. Under these altered conditions a new shaft was sunk in the hanging wall, as an outlet for the ore and for pumping, to a depth of 195 feet. Everything was then prepared for taking out the shaft pillars as well as the balance of the ore. The maximum

THE BEGUELIN PIT MINE, SOUTH CAROLINA.

thickness of the ore body at the Beguelin was 80 feet, and the best ore was found between two large cross-dikes. This mine contains yet large bodies of ore.

A 60-stamp mill was run on Beguelin ores for three years. The Cross mine was then reopened and a drift of 200 feet, made at the bottom of the pits, encountered a dike 25 feet thick, which was cut through and the drift continued for 100 feet more. Four upraises were driven between the two levels one each side of the dike, opening up four large stopes of ore. This ore ran low in sulphurets, but carried more free gold. A new shaft was sunk 270 feet, and a southwest level driven from it found the dike to be 35 feet thick, and no longer decomposed on the wall, as was the case in the upper level. By upraises four more stopes were opened, which furnished ore for the mill.

The ore was of a little better grade in proximity to the dike on both sides. A northeast tunnel 150 feet long in Bumalo pit struck a diabase dike 150 feet thick. The ore was found richest near the dike.

From the 270-foot deep shaft a 600-foot long northeast level opened up large ore bodies in proximity to the 150-foot thick dike, which are connected with the 200-foot level by upraises. The 270-foot shaft was sunk to 370 feet, and from a station at 350 feet a northeast level found the ore to continue below the 350 feet near the dike. Upraises connect this ore with the stopes in 270 feet.

Three different lenses, or great bodies of ore have been found: (1) The Bumalo, farthest northeast. (2) The Haile, or middle lens. (3) A small lens 80 to 90 feet west of the Haile and the Red Hill open pits on northeast side of the 150-foot dike, where ore was formerly mined to a depth of 60 feet. The thickness of these lenses or ore bodies varied, reaching 100 feet in places, in others only 25 to 30 feet.

Mode of Development.—The method of working these large ore bodies is by the pillar system not unlike a great coal mine. The levels 8 ft. $\times$ 7 ft. are run 70 to 100 feet apart and nearer the hanging than the foot wall. At intervals of 50 feet upraises are made with a cross-section 8 ft. $\times$ 7 ft. These are carried forward at 45°. The upper portion through the chain pillar left under each level is carried up vertically. This raise serves afterwards as a chute. Drifts are then run below this pillar until the limit of the slope in length, 30 to 40 feet, is reached, leaving a vertical pillar 15 to 20 feet thick between stopes. The ground is then cut away between the foot and hanging walls, exposing as roof the bottom of the chain pillar, above which it is sprung in the shape of an arch, with its heavier toe on the foot wall at a minimum thickness of 15 feet. This work is all done by air drills. Stopping is then carried downwards by hand drilling in circular steps arranged in such a manner as to allow the ore to drop into the chute on blasting without further handling.

The angle of 45° given to the latter allows a steady flow of the material down the foot wall without completely choking it. At the bottom of the chute is a rough grizzly made of logs holding back the large boulders and preventing them from choking the smaller loading pocket below. This grizzly is easily accessible from the drift, and the larger pieces of ore are here sledged. The loading chute and grizzly are kept up as long as possible until the stope is finally broken through to the drift level below, the ore being shovelled into cars.

Pillars are left in poor ore, if possible, the diabase dike fulfilling this purpose admirably. No timber is used and although chambers 100 ft. $\times$ 100 ft. $\times$ 40 ft. have been cut out, there seems no danger of a fall, the country slate being very tough and self-supporting.

The stopes from the 100- and 200-foot levels are connected with the surface by raises so that at a future date the worked-out stopes can be filled from the surface and the ore in the pillars, that is, what is left toward the hanging wall can be taken out.

Blasting is done with 40 per cent. Hercules powder. One-inch steel is used for hand and 1½-inch for machine work. The number of air drills is limited by the size of the compressor. Driving and raising is done by air drilling, the stopping being done by hand labor. The latest improved Rand drills are used; the one known as the "Little Terror," which has a diameter of 3¼ inches; the air is supplied to these drills by a class C Rand compressor, and an Ingersoll compressor for 10 drills is ready for work when needed.

The ore is carried from the loading chutes to the shaft in wooden cars of ½-ton capacity running on 18-inch gauge track.

At No. 2 shaft (7 ft. $\times$ 12 ft., single compartment) they are hoisted by cage with an automatic safety catch.

The new shaft is 6 ft. $\times$ 14 ft., triple compartment, and the ore is raised by a novel skip designed by Mr. Thies. The body of the skip, made of sheet iron, has two projecting lugs riveted to it below the center of gravity, and the bail is lugged 1 inch from the vertical center line. Each lug runs between a pair of yellow-pine guides set 2 inches apart; when the skip is raised above the landing chute, two iron pins are thrown across the opening between each set of guides. The skip is dropped down on these and the ore is dumped into a loading chute placed on the heavier side of the skip.

The skip is raised and righted by the bail, the iron pins are withdrawn by the top man, and the skip descends.

The operation is rapid and simple, and the cost of the device is light.

The mine is not wet, a No. 9 Cameron pump easily handling all the water. For the details of this account, apart from my own observations, I am indebted to Mr. Thies, as also to the very minute and accurate description, by Messrs. Nitze and Wilkins, in the transactions of American Institute of Mining Engineers, October meeting, 1895.

Coal in India.

Coal is widely distributed throughout India, except in Bombay and Sind, the Northwest provinces, and Oudh, Rajputana and Mysore, where the mineral is either scantily distributed or entirely absent. The seams in Bengal and Assam are frequently from 50 feet and 80 feet to as much as 180 feet in thickness. The pits are often of considerable depth. At present the deepest appears to be about 700 feet. In many cases the working of the seams leads to the escape of little or no firedamp, so that the miners are able to work with naked lights. At the present time Bengal produces more than three-fourths or the coal mined in India. Indian coal varies much in composition and quality. Most of it is quite suitable for ordinary purposes, while some of the samples, e. g., certain of these from Bengal and Central India, are of excellent quality, equal to that of some of the best British

coals. The fixed carbon of the Bengal coal ranges between 50 and 60 per cent., and the calorific value exceeds 6,000 calories—equal to about 10 British thermal units—while the ash often does not much exceed and in some instances falls below 10 per cent., and the sulphur is frequently present in but very small proportion. —*Science and Art of Mining.*

Idaho—A Glance Backward.

Extract from the Report of J. A. Cizek, Inspector of Mines for 1899.

From the date of the first discovery of the precious metals in Idaho in the early sixties to the present, this State has taken and holds an enviable position among the mining States of the West. True, Colorado and Montana seem to have forged ahead more rapidly, owing to the fact that these States for some reason seem to command all the necessary capital to develop the rich mines there, while Idaho, though wonderfully rich in all kinds of natural resources, especially in gold, silver, copper, and lead, did not attract the attention of men of capital until a comparatively recent date, but now that her wonderful properties are becoming known in the centers of the world's commerce, Idaho is rapidly taking the lead.

It may be truly said, without boasting, and preserving conservative limits, that Idaho has a greater wealth of mineral resources than either Colorado or Montana. Her placers have been the wonder of the nation, and are still pouring their millions into the lap of commerce. Her lead mines now produce nearly half of all the lead produced in the United States. Her gold quartz mines have been touched only in places, and her mountains of silver, when justice has been done to the white metal and bi-metallism triumphs, will reveal a wealth as marvellous as that of the Indies.

A conservative estimate of the wealth of gold and silver added to the world from Idaho since the discovery of gold here is in excess of \$250,000,000. Over \$40,000,000 in gold and silver have been turned into the various assay offices of the United States since the organization of the Territory. Since Idaho became a State in 1890, she has produced in gold and silver, saying nothing about lead and copper, \$72,744,575. By years the output of gold and silver, as given in the *Statistical Abstract* issued from the United States Treasury Department, is as follows: 1890, \$6,663,838; 1891, \$6,896,970; 1892, \$6,196,451; 1893, \$6,703,159; 1894, \$6,333,081; 1895, \$5,804,380; 1896, \$8,813,757; 1897, \$8,038,605; 1898, \$8,692,107; 1899 (estimated), \$8,603,028.

The estimate for the year 1899 of the product of gold, silver, lead, and copper is as follows: Gold, \$2,500,000; silver, \$6,103,028; lead, \$4,960,410; copper, \$60,000; or a total of \$13,623,418.

Apart from her large mountains of mineral-bearing quartz, her placers are extensive and valuable. The Snake River bars are rich in flour gold, which modern methods of treatment are now rendering available, and soon this vast wealth of the yellow metal will be poured into the avenues of commerce. With increased transportation facilities and the improved methods of treating the baser ores, the mineral wealth of Idaho will soon be doubled.

In concluding, this report may point out that the exhibit herein made does not do justice to Idaho as a mineral-producing State. The State has been only partially prospected. No State in the Union has more extensive and valuable mineral resources than Idaho. In lead her mines are the greatest in the United States, and when the vast copper properties of the Seven Devils district are developed, as they bid fair to be in the near future, the copper output of Idaho will astonish the world. With the triumph of bi-metallism will come wonderful activity in the rich silver mines of the State; and with even the larger use of silver, the silver output of the State will be astonishingly large. Her gold placers yield large, and her vast gold quartz mines, with modern facilities for working and better transportation facilities, which are sure to come, will double and quadruple the gold product of the State. When the problem of saving the fine flour gold of the Snake River bars has been solved, and these bars are worked, it is impossible to tell how large the gold output of the State will be. The fact is that the output of the precious metals in Idaho is much larger than that given in this report. The report is based on the amount of gold and silver actually accounted for by the United States assay office in Boise, but large quantities of the precious metals are mined here and taken out of the State that are not reported to the assay office at all. There are few smelters in Idaho, and no inconsiderable quantities of gold and silver taken from ores shipped out of the State for smelting are credited to those States where the ore is smelted, and Idaho does not get the credit for them. This State, it seems to me, from a careful examination of the conditions here, is a good point for the establishing of smelters, at least in certain localities. The attention of mining people is respectfully called to this subject.

THE METALLURGY OF ZINC.

The Physical Properties—The Chemical Properties. Zinc Ores—Methods of Reducing the Ores.

The Dry Processes—Wet Processes—Electrometallurgical Process—Processes in Which Zinc is Obtained in the Form of an Oxide or Pigment.

Written for MINES AND MINERALS, by H. Van F. Furman E. M.

(Concluded from August.)

Silesian Process.—This process, which was introduced in the year 1798, is carried out in reverberatory furnaces in which muffles are arranged. The zinc vapors which are distilled from the charge in the muffles are condensed in various forms of adapters. The muffles generally have the form of prismatic boxes with an arched roof, although the roof is sometimes flat and the corners are rounded. The rear end of the muffle is closed, whilst the front end is open. During the distillation the lower half of the front end of the muffle is closed with a fireclay tile, whilst the upper portion is closed by the end of the adapter which is tightly luted on with fireclay. The muffles are generally 26 inches high (inside measurement), 6 to 8 inches wide, and 28 inches to 7 feet long. When the muffles are only supported at their two ends their length should not exceed 4 feet. The walls of the shorter muffles average about 1 inch in thickness, whilst the longer muffles have thicker walls, the bottom frequently being 2 inches thick. The same materials used for the manufacture of retorts in the Belgian process are used for the manufacture of these muffles. They are made either by hand or by machinery, hydraulic machinery being generally adopted in modern works. They must be introduced into the furnace in a red-hot state.

The ordinary Silesian furnace is shown in cross-section in Fig. 4. It is divided into a series of bays on either side of the fireplace, each bay containing two muffles, which rest on the bed, and are consequently heated only on the sides and crown. The ends of the muffles project through the side walls of the furnace into a small outer chamber. The grate is shown at *a*, the muffles at *c*, the adapters at *x*. The adapters are provided with an opening at the bend *d*, which is closed by a plate luted on during the distillation, which serves for the removal of obstructions. The condensed metal flows into the receptacle at *b*. This form of condenser has been largely superseded by other forms which approach those used in the

FIG. 4. SILESIA FURNACE.

Belgian process, being provided with nozzles for condensing the fume, thus resulting in a greater saving of zinc.

The operation is much the same as in the Belgian process and lasts 24 hours. In consumption of fuel and labor the process is somewhat more expensive than the Belgian and the loss of zinc is greater. However, with the introduction of furnaces fired by producer gas and provided with regenerator flues, the fuel consumption is not much greater and an inferior quality of fuel can be used. This furnace is only used for the treatment of poor ores, such as the silicate and carbonate ores of the Silesian provinces, where ores containing 20 per cent. of zinc are treated at a profit.

Belgo-Silesian Process.—The furnaces used in this process differ materially from the older forms of Silesian furnace, the flames not being allowed to escape from the furnace, either through the arch or laterally, but being first made to strike the arch and then to return, escaping at the bottom of the furnace. The products of combustion are led into a common flue running under the hearth of the furnace into a stack, or into several stacks. Sometimes before escaping into the stack they are utilized for heating retorts and calcining ores. The supports for the muffles are made as small as possible, so that the bottom shall be partially surrounded by the flames. In the older Silesian furnaces we have a single row or tier of muffles, whilst in the later Belgo-Silesian furnaces we have several tiers (usually three) of smaller muffles, one tier above the other. The furnaces are fired either by grates or by gas, either with or without regenerators.

Before the furnace is placed in active operation it is heated up gradually for three or four days, when the muffles are put in place and annealed in the furnace itself. The firing is now increased for three or four days, when the muffles are bricked in, the adapters are attached, and the muffles are charged. When the

bellied form of adapter is adopted the charging is done through the front of the adapter, whilst with adapters having the form of inclined cylindrical tubes or of rectangular boxes, the front being closed by a tile or clayed iron plate, charging is done through the apertures left when the tile or plate is removed. The temperature must be kept as uniform as possible throughout the operation of distillation, for if it is too high, uncondensed zinc escapes through the adapters and burns when coming in contact with the air; if it is too low, the zinc condenses as fume, which is partially caught in the adapters and is partially carried off by the gases. After the distillation is finished the zinc is removed from the adapters, the residues are raked out, the muffles are repaired or replaced, and a new operation begins. The distillation operation occupies 24 hours. The weight of charge varies from 60 to 200 pounds, according to the size of the muffles.

A recent form of furnace fired by gas but not provided with regenerators is shown in Fig. 5. The gas producers *p* are located at both ends of the furnace, the air for the combustion of the producer gas being preheated in the walls of the furnace as is shown in the illustration. The muffles *c*, the adapters *x*, and the nozzles *y* are shown in the illustration. The gases after passing over and around the muffles pass into the flues *s* and thence to the stack.

Treatment of the By-Products.—The distillation operation being imperfect, a number of by-products containing zinc are produced. These are zinc fume, (blue-powder) flue dust carrying zinc, the residues from the adapters and the retorts, furnace accretions carrying considerable zinc, and the zinciferous skimmings from the refining operation. The zinc fume is finely divided metallic zinc and generally contains about 10 per cent. of zinc oxide and also cadmium, arsenic, antimony, lead, and other substances which are volatilized from the charge during the distillation. It is generally treated with the ore charges in the distillation furnace, being added in small amounts so that its impurities may be distributed through large quantities of zinc. It is treated in those retorts which are subjected to the lower temperatures. Sometimes it is allowed to accumulate, and at intervals a special run is made of this material and other by-products, the result being an impure zinc. The residues from the adapters and the flue dust, which consists largely of zinc oxide, are generally added to the ore charges in the distillation furnace. The residues from the retorts or muffles contain from 4 to 11 per cent. of zinc. They

FIG. 5.

are sometimes subjected to a dressing operation, the result being concentrates rich in zinc, which are treated with the ore charges. The refinery skimmings, which are rich in zinc, are treated with the ore charges or are distilled together with the zinc fume and the residues from the adapters for an inferior quality of zinc.

Improvements.—The present distillation methods are crude, wasteful, and expensive. As far as the roasting is concerned, the introduction of mechanical furnaces and means for the condensation and utilization of the sulphur vapors have greatly lessened the expense of this operation. The distillation process, however, continues to present great obstacles to improvement. It is a non-continuous process; each successive charging of the vessels necessitates lowering of fires and cleaning of retorts, resulting in a large consumption of fuel and labor. A large quantity of zinc is lost in the various operations. A quantity of finely divided metal and zinc oxide is produced at each operation, and as this has to again undergo distillation the capacity of the distillation furnaces is materially reduced. Another serious objection is that, with the furnaces now in use, ores containing any considerable admixture of foreign sulphides or oxides cannot be treated. Ores composed largely of blende, with an admixture of iron and copper pyrites, and galena carrying some gold and silver are frequently encountered in our mining regions, and as they occur in enormous deposits, especially in the Western States of America, some method for their economical reduction has been desired. The zinc smelters of the United States will at present not treat ores containing to exceed 2 per cent. of iron and 3 per cent. of lead, as these metals combine with the silica of the retorts, forming fusible slags which rapidly destroy the vessels. Ores containing larger amounts of these metals must be mixed with other ores, so as to

bring the percentages of iron and lead within the above limits. In most instances such mixing is impossible, nor can the ores be successfully smelted for lead bullion on account of their high zinc contents. Experiments made in Denver, Colorado, during the past 18 months have apparently overcome this difficulty. These experiments were made by Prof. Benjamin Sadtler, who has recently protected the principles involved by both domestic and foreign patents. It is through the courtesy of Professor Sadtler that I am able to publish the following results and I will quote him in his own words:

"We used a small furnace, containing 30 full-size retorts, which we purchased in Missouri. These retorts were lined by us with various basic ingredients, and after being carefully fired up in the furnace, were charged with ore. We lost, during the entire run of 89 charges, a total of 10 retorts, which were lost entirely by breakage, none of them having been corroded. This breakage was chiefly due to the fact that our workmen were not skilled in cleaning the retorts. This gave us a daily loss of one in 267, or a small fraction of 1 per cent., as over against the daily loss in Missouri, running on ores not containing an appreciable quantity of iron, of 3 per cent. It is my belief, that with properly skilled workmen, we could materially lessen this small loss. The ore which we treated in these retorts was very materially different from the Missouri ore, in which it was their rule not to place in the retorts a charge containing more than 2 per cent. of iron or 3 per cent. of lead, as exceeding these figures makes their loss by corroding too rapid. The ore which we treated ran variously, in the raw ore, from 16 to 30½ per cent. iron, from 1½ to 12.89 per cent. lead, from 2 to 9 per cent. silica, and from 16½ to 37½ per cent. zinc. The silver ran from 5 to 17 ounces per ton, and the gold ran from \$1 to \$11 per ton. The zinc we produced was assayed at the Grant smelter, and by two prominent assaying firms in Denver. It showed no gold or silver, these metals appearing to remain entirely in the residue. It showed variously from 0.52 to 1.12 per cent. lead and from 0.06 to 0.12 per cent. iron, both of these impurities being well within the limit allowed for first-class spelter. The residue was perfectly oxidized, contained some little carbon and all of the gold, silver, copper and iron present in the ore, and practically all of the lead. It contained from 4.2 to 8.5 per cent. of zinc by the smelter returns. As we were obliged to use rather dirty coal-slack in this experiment, we ran the silica in the residue somewhat higher than would be the case in regular practice, where we would, of course, use a washed slack or a selected pure slack for admixture with the charge.

"In regard to the preparation of the ore for the retorting: It requires crushing and roasting. It is not desirable to have too high a percentage of either silica or lead, not that they appeared to have injured the operation of the process to the extent that we did use them, but because it is poor economy to use so expensive a process as distillation on such substances as lead, which would derive no benefit therefrom, or such as silica, which is simply a dead weight. It would be found, in most ores, that it is desirable to concentrate prior to the use of this process, cleaning out such proportions of the lead and silica as can be done without undue loss of values. As the ore has in any event to be crushed before roasting, the concentration would not add largely to the cost of the process."

This process is essentially the Belgian process of zinc distillation with the important addition of a non-corrosive lining to the retorts. As has been previously stated, zinc smelters do not care to treat ores containing over 2 per cent. of iron or 3 per cent. of lead in the Belgian process, on account of the destruction of the retorts. In this process the interior of the retorts is protected from corrosion by the protective lining. Hence, complex sulphide ores, after roasting, may be treated in the Sadtler retorts for the distillation of their zinc contents. The residues carrying practically all of the gold, silver, copper, lead, and iron contents of the original ores are then in excellent condition for the extraction of their gold, silver, copper, and lead by the ordinary process of smelting for base bullion and copper matte in the blast furnace.

The Fry process for the treatment of mixed sulphide ores has been in operation at Swansea, Wales, for some time, but with what degree of commercial success the writer is not informed. The Smelting Corporation controlling the process have erected a new plant, having a capacity of from 100 to 150 tons of ore per day, on the Manchester ship canal, England. The roasted ore is mixed with about 25 per cent. of salt cake (crude sodium sulphate) before it is withdrawn from the roasting furnace. The salt cake, which fuses rapidly, agglomerates the ore which is then smelted in blast furnaces with the addition of a small quantity of iron oxide as flux. The smelting is very rapid and about 90 per cent. of the lead present is reduced and collects most of the gold and silver as in ordinary smelting for base bullion. About 90 per cent. of the zinc present passes into the slag. The slag is pulverized, mixed with fine coal, and heated in a Siemens gas

furnace, where the zinc is driven off as oxide, forming a product containing about 64 per cent. zinc. This product is reduced to spelter by the distillation process. About 80 per cent. of the zinc contained in the slag, or 72 per cent. of the amount present in the raw ore is recovered as oxide. The success of the process naturally depends largely upon obtaining a cheap supply of salt cake.

The Ellershausen process, which appears to be similar to the Bartlett process in operation at Cañon City, Colorado, has had in operation an experimental plant at Llanelli, South Wales, and at Angoulême, where considerable mixed sulphide ores from Broken Hill, Australia, Tasmania, and France have been treated.

Numerous experiments have been made in the treatment of zinc ores in both blast and reverberatory furnaces, but so far none have given much promise of success. The difficulty has always been in keeping the zinc reduced, no method having been so far brought forward for keeping the condensers free from carbonic acid and air. (See The Chemical Properties of Zinc.)

The use of vertical retorts with interior condensers has been proposed, and the endeavor has been made to make this a continuous process, but so far these methods have not passed the experimental stage.

A gas-fired furnace, with highly inclined retorts, has been patented by Thum. This furnace was designed to treat ores rich in lead. The retorts are open at both ends, the lower end being closed with a clay plug and the top end by an adapter. The zinc vapors escape at the top end and are condensed in the adapters, whilst the lead collects in the bottom. This method has not given satisfaction in practice.

WET PROCESSES OF EXTRACTION.

As metallic zinc is not precipitated from solution by any of the metals which are stable in the ordinary temperatures, the wet methods resolve themselves into a combination of a wet method and a dry method, or of a wet method and electrolytic precipitation of the zinc. Numerous wet methods have been proposed, and patented, and a number have been experimented with on a commercial scale, but so far without very promising results. The difficulties to be contended with in the economical extraction of zinc by these processes are: Great cost; the zinc is not obtained in the form of spelter except by distillation of a previously obtained product. Even where electrolytic precipitation is the method adopted for recovery of the zinc from solution the metal is generally precipitated in the form of zinc sponge, which has to be retreated for the production of spelter. With many ores the difficulties attending filtration and precipitation are great. Zinc has been recovered from poor ores and furnace products by means of sulphuric acid, hydrochloric acid, ammonia, ammonium carbonate, magnesium chloride, calcium chloride, iron chloride, and by subjecting the ores to a chloridizing roasting followed by leaching of the zinc chloride thus formed, the products being solutions of zinc sulphate, zinc chloride, ammonio-zinc hydrate, and ammonio-zinc carbonate, respectively. Whilst the combined wet and dry method of extracting zinc from poor ores has not at present passed the experimental stage, it has come into use in a few cases where the object is to separate the zinc, in the form of a commercial by-product as zinc vitrol or zinc chloride, from other valuable metals and metallic compounds. As want of space forbids a discussion of these processes in the present article, the interested reader is referred to Schnabel's Handbook of Metallurgy, Volume II.

ELECTROMETALLURGICAL PROCESSES.

The extraction of zinc by the electrolysis of molten compounds of the metal has so far not been attempted on a commercial scale, although numerous methods for its accomplishment have been proposed. For a description of these methods my readers are referred to Schnabel's Handbook of Metallurgy, and to Borchers' Electric Smelting and Refining.

REFINING OF THE CRUDE ZINC.

In the United States most of the zinc as it comes from the adapters is sufficiently pure, after skimming in the ladles, to cast into bars ready for the market. Such scrap metal as is produced, and any zinc which contains too high a percentage of lead, is remelted in cast-iron kettles which hold about 800 pounds. The melted zinc is stirred from time to time, then allowed to settle for some time, so as to allow the lead to liquefy out to the bottom of the kettle, the surface is skimmed off by means of a perforated ladle, and the zinc is ladled into iron moulds which form it into plates or slabs. If the metal contains much lead this is separated by allowing the melted zinc, after skimming, to stand for from 15 to 20 minutes, almost to the point of solidification, when the greater part of the lead will collect in the bottom of the kettle. This part of the contents of the kettle is kept separate, and if sufficient of this leady zinc is collected it is remelted and treated in the same way. It is difficult to regulate the temperature as it must be kept rather high, but not above a certain limit, or

considerable loss of zinc by volatilization and burning of zinc will result.

Very impure zinc, as that produced in Upper Silesia, is sometimes refined by remelting in a reverberatory furnace, which has a sloping hearth with a sump at the lower end for the collection of the zinc. The raw zinc is gradually charged into the hot furnace and is slowly melted until the sump is filled; the zinc is then rapidly ladled into the iron moulds.

THE EXTRACTION OF ZINC IN THE FORM OF OXIDE OR PIGMENT.

In some places, zinc ores are treated for the production of marketable zinc compounds, such as zinc oxide (zinc white), mixtures of zinc oxide, lead oxide, and lead sulphate (pigment), or zinc sulphate (zinc vitriol). For these processes, ores are selected which are not generally suitable for the extraction of metallic zinc, either because they contain other valuable or detrimental metals, as manganese, iron, lead, or silver and gold, or because they contain too small a percentage of zinc. Such ores are generally zinciferous iron manganese ores, as the franklinite ores of New Jersey, or complex sulphide ores carrying gold, silver, lead and copper, as the ores treated at the works of the American Zinc-Lead Smelting Co., at Cañon City, Colorado, or the complex sulphide ores of Rammelsberg, which contain considerable quantities of galena, iron and copper pyrites, and barytes, in addition to blende.

The production of zinc white from the New Jersey ores has been brought to a high state of perfection by the earlier inventions of Samuel Wetherill and the later inventions of his son, J. P. Wetherill. At present these ores, which consist of mixtures of franklinite, willemite, zincite, and gangue, which latter is essentially calcite but contains also rhodonite, garnets, and numerous silicates, is crushed, dried, pulverized, screened, and passed over Wetherill magnetic separators. The product of the Wetherill machines is fairly clean franklinite and a mixed, or middle, product of franklinite and various iron and manganese silicates. The tailings from the magnetic separators pass to wet jigs, where the willemite and the zincite are removed from the calcite. The concentrates from the Wetherill machines are sent to the zinc oxide works, and the concentrates from the jigs (principally willemite), which carry about 50 per cent. of zinc, are at present shipped to Germany, where they are treated by distillation, the product being a very pure spelter. The franklinite concentrates are treated for zinc oxide in Wetherill furnaces upon a grate, or upon a bed of fine anthracite coal resting upon the grate, zinc being thus produced, but being immediately burnt to oxide by the air and the carbonic-acid gas contained in the products of combustion; the zinc oxide mixed with the products of combustion is cooled down and collected in bags after the zinc has been completely burnt, and particles of coal and ashes have been separated from it, whilst the permanent gases evolved escape through the pores of the bags. In addition to the zinc oxide collected in the bags, an impure zinc oxide, forming from 2 to 3 per cent. of the total quantity produced, is collected in the flues, pipes, towers, and cooling chambers. This is generally removed once a week, and is either sold as inferior zinc white or is returned with the ores to the Wetherill furnaces, or is distilled in retorts for metallic zinc. The white deposited in the bags is removed from them by shaking and beating at intervals, and is collected in barrels. The residues contain from 1.2 to 6 per cent. of zinc, and as they are rich in iron and manganese, they are smelted in blast furnaces for spiegeleisen.

The Bartlett process in use at Cañon City, Colorado is, in its simplest form, as follows: All ores containing 20 per cent. or more of zinc are crushed to pea size, mixed with 10 to 25 per cent. of pea coal and dust coal, and blown up in a specially constructed furnace, using a blast of from 4 to 8 ounces pressure. It requires from 20 to 40 minutes only to drive off the lead and the greater part of the zinc and sulphur. A cinder is formed containing the silver, gold, and copper, in a matte mixed with more or less slag. This cinder is smelted in an inclined low blast furnace mixed with other suitable ores and fluxes to produce a high-grade matte. The zinc in this charge may reach from 15 to 20 per cent. and is mostly driven off as fume. The fume from the "blowing-up" furnaces and from the blast furnaces is caught in bags, mixed and refined in a suitable furnace, whereby carbon, arsenic, sulphur, and other impurities are eliminated, and a pure white pigment is produced, suitable, after being ground in oil, to be used as a white lead substitute. For a full description of this process the reader is referred to an article by Dr. Bartlett in *Mineral Industry*, Volume V. A similar process is in use at Joplin, Missouri.

At the Herzog Julius Works, at Goslar, and at the Sophia Works, near Langelsheim, zinc vitriol is produced from the mixed sulphide ores of Rammelsberg, which have been previously mentioned. The ores are calcined three times in heaps, by which a portion of the zinc sulphide is converted into a sulphate. Each heap contains about 500 tons of ore. The small ore, which is

separated after the various fires, contains the zinc partly in the form of neutral zinc sulphate and partly as a basic sulphate, which latter is insoluble in water. In order to remove the neutral sulphate the small ore is leached with hot water and waste solutions. The residues, after drying, are smelted for lead in blast furnaces, together with the lump ore from the third fire. The ore is leached four times, the two first times with the unsaturated solution from a previous operation, the two last times with hot water. The first and second solutions are mixed so as to produce a lye of 30° B., clarified, free from iron and sulphate of lime, and then evaporated down to the crystallizing point, when the zinc vitriol is allowed to crystallize out. The mother liquor is pumped back into the evaporating pans until it becomes too impure. A part of the zinc vitriol is worked up into calcined vitriol.

Mining in British Columbia.

Extracts from the Annual Report of the Minister of Mines, of British Columbia, as given in the U. S. Consular Reports, give the following facts:

The total mineral output of the Province for the year 1899 was \$12,393,131, as against \$10,906,861 for 1898, an increase of \$1,486,270, or 13½ per cent.

This would have been largely increased but for the shutting down of several mines, owing to the passage of a law prohibiting miners working over eight hours under drastic penalties, which completely demoralized the industry for some months, causing a deficit of \$910,844 in silver and lead values alone. It is believed that but for the shutting down caused by the legislation referred to (the penalties of which have recently been temporarily suspended), the same mines would have brought an increase of \$500,000, instead of the present deficit, making the years' increase \$2,863,159, or about 27 per cent. over last year.

The coal mines of the Province during 1899 turned out 1,306,324 tons of coal and 34,251 tons of coke, an increase over 1898 of 170,459 tons of coal and a decrease of 750 tons of coke. The total value of coal produced in the Province during 1899 was \$3,918,972.

The gold production for 1899—including both placer and lode gold—was \$4,202,473. The yield of placer gold was \$1,344,900, over double that of 1898, when the yield was \$643,346. The large increase was due to the discoveries in the Atlin Lake district, which, notwithstanding the disadvantage of the disputes regarding ownership caused by the enactment of the alien law, yielded \$800,000 in gold. The output of gold obtained from lode mining in 1899 was \$2,857,573, an increase over 1898 of \$656,356.

The amount of copper produced during 1899 was 7,722,591 pounds, an increase over 1898 of only 6 per cent. As yet, the copper-mining districts are practically limited to three—Rossland, Nelson, and the west coast of Vancouver Island. Rossland produces 75 per cent. of the total output of copper in the Province.

There has been a material decrease in the amount of silver produced in British Columbia, owing to the fact that the largest producing mines have been shut down since June or July, on account of labor troubles, as stated above. The total silver production for the year amounted to 2,939,413 ounces, valued at \$1,633,708, a decrease from the production in 1898 of 1,357,619 ounces fine silver and of value \$712,133.

The total lead production for 1899 amounted to 21,862,436 pounds, valued at \$878,870, as against 31,693,559 pounds, valued at \$1,077,581 for 1898, a decrease of 9,831,123 pounds of lead and of \$198,711 in value.

Some 2,000 tons of iron ore was mined in the Province last year—near Kamloops and on Texada Island—which was used for fluxing purposes by the smelters.

Lake Ore Matters.

The attitude of the Rockefeller interests in iron ore is the interesting question to all buyers of ore, as this company is far and away the largest seller of ore on the American market today. When this company offer to sell their best ore, a standard Mesaba, at a price on dock, Duluth, that returns no more than cost, and offer to contract any amount at this price for a term of years—as they are doing today—their position becomes of supreme importance. If they can sell every ton of this standard ore at from 50 cents to \$1 a ton above the price they offer, and that is the fact, why are the low figures made? The question is not a hard one to any man from the oil region, for instance. Cost, in the case of any Mesaba ore mined by companies controlling their own railways to Lake Superior, includes an 80-cent rail freight, in which is the very fair profit to the combination of mine and road. But to any independent miner not controlling a railroad this 80 cents is an actual charge. It is, therefore, to the interest of the Rockefeller company to keep freight rates by rail where they now are so long as possible. And by the same token it is their interest to hold up lake freights.—D. E. W. in *Iron Age*.

DRAINING GAS FROM GOB WORKINGS.

By Bore Holes—Where It Is Practicable—The Relative Advantages of Force and Exhaust Fans for This Purpose.

By Chas. Connor, Mine Inspector, Uniontown, Pa.*

This subject was discussed by this Institute at a previous meeting but was not finished, and whilst getting up this program, the time for which was limited, and to get enough papers was a matter that required some time, Mr. Fohl, the secretary, suggested that I take up this subject again. This is not so much in the nature of a paper on the subject as some thoughts that would lead to the discussion of this question. I have talked on this matter before and have had some experience possibly in regard to these matters, and I simply want to give you the benefit of my experience, what I have seen, what I know, and whether they would be productive of the results that have been claimed for them or not, and, as the subject indicates, whether or not it is a practical method of removing gas by means of bore holes. I have had some other thoughts which I desired to embody in this paper but was not able to finish it on account of the great pressure of other work to which I had to attend. What I have read* I will now supplement, in a disconnected way, perhaps, with some remarks in addition to what I have written.

I had expected to write some particulars with respect to the territory drained as well as the quantity of gas given off, the depth of the seams, and of the bore holes, which may be of interest, and last, but not least, something with respect to the cost of them. The bore hole described in my previous paper, the first one (three of them have been bored into this mine), was of a depth of about 300 feet and was 6 inches in diameter. It was drilled down from the surface until it reached the top of the fall.

Previous to this bore hole being put down, a current equal to 35,000 cubic feet of air per minute, was passing through the heading, and this failed to remove the gas in the gob. I measured this current two days previous to the hole being put down, and found that there was so much gas being given off that in that current of air, at a distance of about 50 yards along the headings from where it came out from the gob workings, gas could be detected in the entry by exploding in the safety lamp two feet from the roof of heading.

After the hole had been drilled three days I again visited the mine. The same current was going. I went into the places where I had found gas down below the roof from 1 to 2 feet, and out in the entry. When I went back the second time I went up at least 45 to 50 feet on the top of these falls—just as far as I was able to get—and I was unable to detect the presence of gas in these falls in any place that I could get into. Now, a fact like that is very much better than any theory and, as an illustrious person once said, it was "a condition confronting us, not a theory".

Before the bore holes were put down, gas was found in the gob fall in such dangerous quantities that it was absolutely dangerous for men to work in that portion of the mine, or indeed, in the adjacent portion by reason of that gas. Three days after that bore hole had been put down, the presence of gas could not be detected at all, showing clearly that this was a very effective means of removing the gas from that fall. The extent of area that was drained off was in the neighborhood of about 16 acres, and previous to the bore hole being bored we could get gas in any place around the edges in that area of 16 acres and from 1 to 2 feet below the level of the roof. Three days after it was put down we couldn't get it at any place, showing that it was draining off about 16 acres of territory, thereby proving conclusively, in that particular instance, the effectiveness of this method of removing gas.

In another portion of the mine a second bore hole was put down and under somewhat different conditions. They bored this hole 380 feet, drilled it down through into the coal before the pillars were withdrawn, with a view to draining off the gas from the strata. The result of that experiment was that it did not accomplish what was intended. The size of the hole was the same as the first one, 6 inches. A feeder of water was struck in this hole, which came down in considerable volume, equal to about 100 gallons a minute. The volume of that water coming down created enough suction to overcome the pressure of the force fan that should have taken the air and gas up through the hole. A considerable volume of gas was also drained through the strata with the water, and for a distance of about 20 feet around the bottom of bore hole a safety lamp would be filled with explosive gas. However, that did not appreciably affect the amount of

gas that was in the gob workings about this bore hole. It was still found about the same place, and it continued that way until pillars were worked back to where the bore hole was located and a fall made in the roof and the solid stratification broken, which distributed the force of the water that was coming down the hole, and at the same time made a reservoir for the gas immediately under where the hole was. After that was done, the stratification broken, and the gob made, then the gas in the gob began to diminish in volume, and gradually became less and less, and ascended higher in the falls, until, I think in about three weeks' time, if I remember right, we were not able to detect the presence of gas in that portion of the gob at any point within reach. This second bore hole seems to demonstrate this fact: That in order to be effective, three bore holes must be bored over falls or gob, and that the gas cannot be drained off through strata which are unbroken.

A third bore hole was put down some time last year, about June or July, 1899. This third hole was bored 370 feet in depth and was also 6 inches diameter, and was drilled down onto the gob, as had been the first. It was a part of the mine where they had reached the boundary line and had nothing but gob behind them, and no means of getting in between or behind the falls in any way to eliminate or carry off the gas. When the pillars had been extracted back some distance the gas seemed to increase very much; at first they did not have very much and could work along safely, but by and by it came lower down upon the falls until it got below the roof 18 inches, and 2 feet in some places, and it was with very great difficulty they worked. Indeed, they had to stop a number of places because it was not safe to work, and they could not put a sufficient amount of pressure by ventilating power in there to remove the gas from the gob, it simply removed a little from the outer edges of it, and there seemed to be volume enough of gas in the gob to supply more than the air was able to take off.

The third bore hole was put down, as I said, 370 feet in the same manner as the first one on the top of the fall or gob. A few days before this hole was down I measured the air current as before, and found it was 40,000 feet in that section of the mine. I discovered the fact that even when this latter current was circulated, they could not control nor keep in subjection the volume of gas generating in the gob, and they had to abandon part of the workings of the mine. A week after this hole was put down, I went up on those falls again as far as ever I could possibly go, 35 feet, at least, and I could not get any gas, was not able to detect gas by a safety lamp in any portion of that gob working, showing that in this case it was very effective, that it had the desired effect in removing the gas.

In the first bore hole that was put down I took samples and tested it on the Shaw gas-testing machine. The velocity of the air passing up was 2,000 feet per minute through the 6-inch bore hole, and when I tested the samples there was 50 per cent. of gas passing through that bore hole, showing that there was a large amount of gas. I have not made any tests of the other holes; however, there is not any question but that there must have been gas carried off, because it took it away from the mine.

Between the time of putting down the first bore hole in the Oliver mine and the putting down of the third, two more were put down in other mines in my district. Each of these was over 500 feet in depth. I might say, however, that the area of the territory that was drained by the second Oliver hole was about 12 acres, and the area that is being drained now in the third hole is about 5 acres, which territory they are still working at, and how much area it may drain before it becomes more effective, we cannot, of course, tell. The holes that were put down in Leisenring No. 3, were over 500 feet in depth and 7 inches in diameter, and drained about 13 acres of gob in each case. They were put down, as was the second hole at the Oliver shaft, into the solid coal before the gob or pillar workings had been worked to the point where the bore hole was located, and in each case, as in the Oliver second bore hole, they did not diminish the amount of gas that was in the gob until after the pillars were extracted and the falls made where the hole had been bored down. However, there was this difference, in each of these holes at Leisenring they did not have any water and there was a natural draft up both holes. In the second hole at Oliver, where the feeder of water was struck, there was a draft down against the air which brought the gas down; but in these two the draft was upwards through the hole and yet they didn't seem to diminish the quantity of gas in the gob workings until the falls were made back around the holes, after the pillars had been extracted. Now this shows, if it shows anything, that the value of bore holes for this purpose depends upon putting the holes down over where an excavation has been made, and that a hole will not drain off gas through the unbroken strata. It is reasonable to think that this is the case; because the pressure that would be necessary to force the gas from the gob through the strata to the bore hole would be very much greater than the pres-

*The preliminary part of this paper, which was read before the Central Mining Institute of Western Pennsylvania, December, 1899, was published in MINES AND MINERALS, June 1900.

sure producing ventilation in the mine. As a matter of course it would seek the least resistance, and of course, having greater resistance to meet through the solid strata into the bore hole it will not go there, but will fill up the gob and give off the surplus into the air as usual. What I mean is this: Where a bore hole is being put down ahead of where gobs are being made, or where pillars are being drawn out, it will not liberate the gas from that gob working until the pillars are extracted and the strata is broken and an excavation made into the bore hole. The pressure necessary for the gas to escape into the bore hole passing through the strata will be greater than the pressure that is keeping it in the gob by the ventilating pressure of the mines, and therefore, until the pressure is reduced to such an extent that it will be less than the ventilating pressure in the mine, it will not escape through the solid strata; but immediately after the pillars have been extracted and falls have been made around where this bore hole is located and the bore hole is opened to the fall and the pressure of the atmosphere can get at the gas on the fall and force it up the bore hole through the falls and not through the unbroken strata, then it will be removed, and it did so in both of these instances at Leisenring as well as in the cases at Oliver.

Now these facts go to show that this is a practical method of removing dangerous quantities of gas from mines where there are large gob areas filled with explosive gases, and that cannot be worked for that reason, and permits the danger to be removed and allows them to be worked safely.

An objection may be raised as to the cost of this method. If you take into consideration the area or the acreage that has been drained, and take the cost of a bore hole and divide that by the tonnage of that acreage, you will find that it is a very insignificant expense. Take a coal seam where, for instance, about 12,000 to 13,000 tons per acre are extracted, and multiply that by 10 or 16 acres. The cost of the bore hole would be about \$1 a foot. Even in these two cases, where the holes were 500 feet deep, the cost would be only \$500 each. Now divide \$500 by the tonnage of 16 acres of coal, and the result is so small a fractional part of a cent per ton that it is not worth speaking about. The cost, when figured out, is as follows:

Tonnage in 16 acres = 208,000 tons; bore hole cost \$500,
 hence, $\frac{500}{208,000} = \$0.0024$ per ton.

And when you compare the safety that is secured with the money that you expend, why then, there is no room for argument at all, there is no room for objection at all, because in several of the cases portions of the mine were stopped and could not be worked because of their unsafe condition, and by this means they were freed from that danger and were able to be worked, and to be worked safely; why the question of cost should not be a consideration at all, especially when it costs so little.

Then again, it may be objected that this method is only efficacious where we have a force fan. In other words, it may be said that where there is an exhaust fan that would tend to draw the air current down through the bore hole into the mine, it would have a tendency to bring the gas off the gob into the air current of the mine and thereby make it more dangerous than it was before. That may seem very plausible at first sight, and may be looked upon as a valid objection, but if you look into it I think you will find that it is entirely fallacious. If the gob workings are filled up with gas, and if the pressure is in excess of the ventilating current, the gas distributes or diffuses itself into the air current, mixes with it, and is carried through portions of the mine anyhow, even when you have no bore hole. If you have a bore hole, and the air is going down through it and into the workings of the mine, you would not have any more gas coming into the atmosphere than was in the gob, and the gas would not be any greater than it was before, after the gob was once cleaned. But if that argument is good, let us pursue it a little further. The air goes down the bore hole and brings out the gas from the gob; it is evident, if it brings out more than was formerly going into the atmosphere of the mine, it is bringing out some of the surplus, and it is leaving less gas in the gob. It may be that it is mixing with the atmosphere in greater volume than before, but by and by, if it comes with the air long enough, it will clear the gob of gas altogether and keep out the large accumulation that you have hitherto had in the gob, and therefore you have less danger even under that supposition. Even supposing that it is a down throw, and with an exhaust fan you will simply have the feeder of gas that is being generated in the gob given off into the atmosphere of the mine, and you have no reservoir of gas in the falls whatever. If it does not bring any more out than it did before, it is not adding to the danger, so that, therefore, you cannot increase the danger by any species of argument whatever on that ground. And then what is left to be done? Why, it has been demonstrated that you can remove it, and it has, in every instance, by using a force fan instead of a suction fan; simply convert your suction

fan into a force fan. With these remarks I will open up the way for discussion.

I think in any other location in the Connellsville region we could attain the same results we did at the places mentioned. The gas would only be uncontrollable until the gob would be cleared of the gas, by the air coming down the bore hole, when the feeder only would be given into the air current, as was the case before the bore hole was drilled, with this advantage that the gob would be empty instead of full of gas as was the case before the hole was put down.

Mr. Connor's remarks brought out the following discussion:

MR. ADAMS.—Mr. Connor, you said in order to make this method effective you have to bore right into the reservoir, that is, into a cavity, and unless it goes into a cavity then this method will not answer.

MR. CONNOR.—The bore hole should enter directly into the reservoir or cavity containing the gas and not into the solid pillar surrounding the gob.

MR. KEIGHLEY.—Without any other pressure than that of itself, we have gas being produced. There are holes drilled down into the solid strata, and why should not there be force enough behind them to drain that territory, if the gas has lodged in the upper strata in those reservoirs, because it has produced that gas and it has lodged in both the upper strata and lower strata. It is not liberated there, until the strata have been broken or cut. Now would it not be a fact, or is it not a fact, that you can drain the gas from that territory if you drill down through the strata if you strike fissures or the lodging places for this gas. Is not there force enough behind it of its own pressure to drain that territory. Are not there gas wells in this vicinity that are producing 300 or 400 pounds pressure?

MR. CONNOR.—It is true that we have bore holes from which gas is coming in the natural gas fields, but that is because there are no excavations down where that gas is coming from, and it is held by the pressure of the rocks and the bore holes are the only means of escape through which it can get, consequently, it comes from those bore holes. In the experiments that have been made, when the hole was bored down through the solid strata into the coal seam there was some gas coming through the strata, some of it coming up through the bore hole, but it did not diminish the quantity of gas that was away back in the gobs, for this reason, that it took more pressure to force the gas through the stratification into the bore hole and it would require more pressure to do that than was being exerted by the ventilating power, or in other words the ventilating pressure was less than was necessary to bring it through the strata into the bore hole, and therefore, that being less, the gobs were kept full and the surplus escaped back into the mine, just as it had been doing before. But immediately the stratification was broken and the resistance lessened to allow it to escape into the bore hole, then it escaped through the bore hole out to the surface. The unbroken strata through which the bore hole is drilled will not drain the gas from the gob workings beyond the point where it has been broken. You understand it is quite a distance away from the bore hole through to where the fall is, and the gas from the gob will not go through that solid stratification into the bore hole, because it would take more force to do that than it would to go back into the atmosphere of the mine. There is some gas that escapes through the solid strata into the bore hole from the solid strata itself, but not the gas back in the gob, because it has less resistance to get into the air.

MR. PETERS.—What acreage would one of these bore holes drain?

MR. CONNOR.—With the first hole we had 16 acres.

MR. PETERS.—What would you consider the capacity of one of these holes to take off gas?

MR. CONNOR.—One of these holes, with the conditions existing in the Connellsville coke region, would drain from 10 to 12 acres of coal territory.

MR. PETERS.—What would you consider the effect of a hole under the following circumstances. You have an exhaust fan and the elevation at the pit mouth is, we will say 1,000 feet, and your mine is a sloping mine, your lowest elevation being 850 feet and the point at which it would be necessary to locate your bore hole in order to reach gob workings would be at an elevation of about 1,250 feet. With an exhaust fan, under these circumstances what would be the effect of a bore hole?

MR. CONNOR.—The effect, in my judgment, would depend upon the laws of natural ventilation, and would change as the temperature outside changed so that at times the gas would go out the bore hole, at other times go into the mine. There are other conditions that might come in which would modify that. On the top of the falls, in our region, we have a great deal of heat generated, and from the fact that firedamp is lighter than ordinary air and also because of the fact that it lays away back up in a still atmosphere, it would tend possibly to go up naturally

because of its rarefaction; it would not come down into the heavier atmosphere of the mine unless the pressure of the fan would counteract the motive column due to the temperature of the gas. That motive column would have a tendency to counteract the influence of an exhaust fan in bringing the gas down into the mine. It is a question whether the one wouldn't balance the other, according to the conditions. If you had an inch of water gauge, and an exhaust fan, and you had a very high temperature in your gobs and that lighter air up in there—it is generally away from any current—it is a question to me whether that light air would not go out against the operation of an exhaust fan. But that is not really a question of speculation but a question for demonstration by calculation. As I said in my remarks the gob or fall is full of gas to begin with, before you put that bore hole down. Now, even at the worst, if it brought the gas out of the gob into the atmosphere of the mine you would only have the original feeder of gas circulating through with your air current, which you had before you had the bore hole, and if you clear your gob of gas, you take away the reservoir, which is the element of danger. Now if the bore hole by means of an exhaust fan cleared the gob and forced the gas out into the current of air it would be only for a limited time until the gob was cleared of gas, and you would simply have the feeder then being brought into the atmosphere of the mine that you had previous to the bore hole being put there. Now, if you can work your mine successfully with air that has been diluted with the feeder of gas and eliminate the danger of having a large volume of standing gas, even in that case it would be an advantage. But with the appliances we have today, where we can change by the shutting of a door from one system of ventilation to another, that ought not to be a question to be considered. With even an exhaustive method of ventilation you have the danger removed, and you only have gas that has been diluted with the air current in the mine.

MR. PETERS.—Which did you use, a blowing fan or an exhaust fan?

MR. CONNOR.—We had a blowing fan.

MR. KEIGHLEY.—Do you know that with those fans the water gauge is only $\frac{1}{8}$ of an inch. Suppose you reverse the fan, you would only have twice that amount of pressure, that is, you would only have $\frac{1}{4}$ of an inch water. Where do you get your pressure? There is only $\frac{1}{8}$ of an inch water gauge in it; if you reverse that you certainly could not have any more than $\frac{1}{4}$, and in the suction fan or exhaust fan that is not enough to overcome the gas; that is a matter of calculation. With the style of fan we have I do not believe we can get up power enough to reverse that current. I do not think it is possible, because the hole is only 6 inches in diameter; the friction in that hole is so great that the exhaustive power would amount to nothing at all.

MR. ADAMS.—With your experience in the working of the Connellsville coal, could not the coal be extracted on such a method that you would not have those reservoirs of gas?

MR. KEIGHLEY.—No sir, you cannot do that. They say that by going right up to the surface you let the gas escape. It will not do it in our district. We have broken our cover right up to the surface and still we have gas right down in the mine. We have a stratum of hard rock and a stratum of soft rock, and we have falls right at this very time in the second section, No. 2, Oliver mine, 600 feet deep. That roof is broken clear to the surface and still there is gas there level with the roof in the workings.

MR. STREET.—Under the system of ventilation given, with the air current sweeping at a rate of 40,000 cubic feet per minute along the edges of these fallen places, we find when we liberate the gas that the current will go so far past the last breakthrough and then forms a wall and holds the air at bay. Now then, if you will agree with me in that, I hold that the gas that was above these falls and gobs was simply held there in suspension by the pressure of air below it.

MR. ADAMS.—I don't understand that.

MR. STREET.—The air will only go so far, I don't care what ventilating power you use. It will only go so far beyond the last breakthrough. If the exhaustive current was sufficient to create a down current in the bore hole then it must bring the gas from the top of those falls and distribute it into the air current. But with a forcing ventilation the opposite is the fact. The light gas is located so many feet above the current that is flowing all around it, or flowing in front of it. Now then, you have provided a vent for that lighter gas to escape, and what can it do but go. It is like the Irishman said about Niagara: "There is nothing to hinder it." In our anthracite region we have to carry air up chutes, and some of them are very steep. Why could not air be carried into the falls and those currents kept separate, if possible, from the ventilating currents and the air or the gas carried through there? Section 5 of the law provides that you shall not have this gas

standing. What I want to present is this: That with a forcing ventilation I believe that this is possible, that it has been done, and the gas is more easily removed than it could be, perhaps by any other system, unless in the case of Mr. Keighley, who tells us that he has only about $\frac{1}{8}$ inch water gauge. If Mr. Keighley was capable of producing a current sufficient to sweep those gobs and bring that gas into his mine in his air current, dilute and carry it off safely, that would be the proper method. In my experience in this section, in liberating and carrying pent-up gases with an exhaustive ventilation I have found blackdamp a great deal worse to contend with than the gas that was in the gobs, have found it more dangerous and harder to overcome.

I have in my mind the same thought that Mr. Adams has: A bore hole drilled in solid strata will emit gas 2,100 feet down in solid strata, and it will emit it continuously for years, and burn for years. Now comes the question: Why won't the bore hole at Oliver do the same? The reason that it did not do it, the reason that it cannot do it, and the reason that it won't do it is, that the air coming in keeps the gas in suspension or abeyance, and the water falling down prevents it from escaping. It couldn't have come through the solid strata to the bore hole because the air was in the mines. It did not escape from the solid strata into the hole because it was held in abeyance or in suspension by the air by which it was surrounded. While this may be possible, while it may be practicable with a forcing system of ventilation, I would not regard it as practicable with an exhausting ventilation unless the ventilation coming from this section of the mine was kept in a separate current and liberated in safety beyond the workings and the workers, unless diluted with a sufficient quantity of air to make it non-explosive. If that air could be carried off by suction, exhaustive ventilation, and kept in a separate current, the expense of the bore hole will be obviated. And, as I take it, with the ventilating current necessary to remove this gas, would it not be better to remove the gas in the ordinary way than by these bore holes?

MR. KEIGHLEY.—Mr. Street speaks about removing the gas by forcing ventilation. We tried that. We went to the next section beyond the first fall and opened through the barrier pillar (100 feet thick) and brought the current of air over the gob, and we had to take the men out of the mine. It simply bored a hole through the cavity and took what gas it could reach and left the rest right there. Mr. Ross, mine inspector, was the man that did it. He was then mine foreman of Oliver mine. We did not resort to the bore hole until we had to, because it was a pretty expensive matter, and it was in opposition to the judgment of the mine inspector of the district at that time, Mr. Duncan, Mr. Connor's predecessor. Before we put down this bore hole we discussed the matter pretty thoroughly; we did not put it down in a day, we talked about it probably a year. Mr. Duncan went to every mine in the region where there was a bore hole, and he came back and told me that in every case, whether the mine was ventilated on the forcing principle or the exhaustive principle, the current was invariably down, and he told me, told Mr. Ross, and told a number of others that there was no use putting that hole down, that when we put that hole down that it would be a down-cast, while we had a great volume of air there, we would not have enough water gauge to overcome the down pressure. In the meantime Mr. Connor was made inspector (succeeding Mr. Duncan) and we put down the bore hole. So far as expenses are concerned, I think we spent 10 times as much money as that bore hole cost, to get rid of that gas by bratticing and changing air currents. Mr. Ross has had 20 men there sometimes, trying to force out the gas, and we have shut off the whole mine and even put the whole ventilating system in one current. We have no less than 17 overcasts. Before we put down our third bore hole we had a 10-foot and a 20-foot fan. I came down to Pittsburg and told my employers the condition we were in. They told me to get another fan. We had that fan shipped from Brazil, Ind., by express. The express charges were more than the cost of the fan. We put up the third fan, and still could not do anything. We went back to the old plan (the bore hole), a plan that has been recommended by everybody, and in three days after it went through we had no gas. When that bore hole went down into our mine, the velocity of the gas escaping up the bore hole was 2,000 feet a minute. As to the limits of one of those bore holes, nobody knows it. Sixteen acres is not in it; 16 acres is what we have drained of gas at one time by bore holes. I think we have a territory of 1,400 acres, and I do not believe we will ever have to bore another hole. You had better put in three bore holes to 1,400 acres. I never expect to have to put down another one in that territory. We have gone to our boundaries and we cannot go any farther, we are back from our boundaries in some cases 800 or 900 feet, so there is not any use in talking of 5, 10, or 16 acres; I do not believe anybody knows what a bore hole will drain.

MR. DE ARMITT.—Have you ever tested to see how much gas was coming out of the pipe?

MR. CONNOR.—I said the velocity was 2,000 feet per minute, and I measured 50 per cent. of gas coming out of the hole.

MR. KEIGHLEY.—When the first hole was put down I went to the driller and told him to move his boiler back and he did not want to do it. I told him if he did not I would have the mine inspector on him so he finally removed his boiler and we laid a steam pipe about 1,000 feet, I think on the ground, to that well. We got the hole completed and everything went all right, then some boys came along and set the gas on fire. In the third hole, the men that drilled it were old experienced oil- and gas-well drillers, but I told them about their boiler. I said "You will have to be careful when you strike through into that gob. Gas will certainly reach your boiler." They said, Oh, no, they knew their business, that they had had experience, and said their boiler was far enough away. They struck down into the gob and we took those measurements and they stopped work that day. The next morning they started to take down the rig, one went up on the derrick and the other one started the fire in the boiler and away went the gas. In that case the length of flame was 50 or 60 feet, so there is no mistake about what came out of the hole.

MR. DE ARMITT.—How long did it continue to flow at that rate?

MR. CONNOR.—The last measurement was 900 feet.

MR. DE ARMITT.—What percentage was gas, and if there was no gas, was there not air escaping?

MR. KEIGHLEY.—I do not think there is any air coming up, we cannot get back of the gobs any more, after we get two or three falls with our roof the gob is packed tight.

MR. DE ARMITT.—I understood Mr. Connor to say that 50 per cent. was gas and 50 per cent. air.

MR. CONNOR.—That was at first, in the first hole. I am speaking of the present time.

MR. PETERS.—Would you consider an exhaust fan the proper method of ventilating a mine where there were bore holes to allow gas to escape, or, in other words, would you use an exhaust fan?

MR. CONNOR.—I would not like to put it that way. If a mine was equipped with an exhaust fan I would do just exactly as was done. I am satisfied that is the way to get rid of the gas. If we had a propelling fan in which you can get a water gauge of 10 inches, that would be a different question, but with an exhaust fan of usual type you cannot get a water gauge which will prevent the gas escaping up through the bore hole.

MR. BLICK.—Putting the question more direct: In case you have bore holes to allow the gas to escape, what is the proper method of ventilation, force or exhaust?

MR. CONNOR.—Did you say if you have bore holes for the purpose of allowing gas to escape, what is the proper method of ventilation, force or exhaust?

MR. BLICK.—Yes.

MR. CONNOR.—A man does not generally change his fans to suit bore holes. A man would hardly change his ventilating system for the sake of putting down a bore hole. I would not reverse my fan because I put down a bore hole. The great trouble has been this: It is not for lack of volume of air in circulation that accumulations of gas exists in gob, but it seems when you turn a current of air into a large body of gas it simply bores a hole right through it, it just goes through it and it takes what it can reach and leaves all the corners. That is what everybody experiences in every-day ventilation. You can ventilate right around the faces but you cannot reach back. And the same holds good in a large gob. You can only reach the gas as far as your power will reach it and no more.

MR. SEDDON.—Mr. Connor, you being fully aware of the conditions and circumstances in connection with the Umpire mine immediately after the explosion on September 23, 1898, and owing to the fact that gas in that mine is in about the same quantities at the present time, do you think that a bore hole would have relieved this mine of the gas?

MR. CONNOR.—With the conditions there, not having very much water gauge or ventilating pressure, I am inclined to think that part of the mine could have got relief from gas by a bore hole, due to the head of motive column that would have been obtained in that portion of the mine, and the gas there would not have come out into the atmosphere of the mine but would have gone into the bore hole, even with the exhaustive system of ventilation. I do not remember what the water gauge was, but I do not think it was over $\frac{1}{8}$ or $\frac{1}{4}$ in., and a bore hole there would have practically eliminated the gas from those gob workings.

MR. SEDDON.—I visited the Umpire mine two weeks ago and I found gas still present. Now that covers an area of more than 4 acres, it is not far distant from the place of the explosion. Do you think it would be advisable to put down a bore hole yet?

MR. CONNOR.—Yes; I simply answer that question by repeat-

ing what I have already said. A bore hole there would be an effective means of draining off the gas out of those gob workings, provided they are all connected. Let us understand the position. The condition in the Umpire mine and the conditions in the mine that I have referred to are entirely different. In the Umpire mine they are not properly gob workings in the sense that we talk of gob workings. When we talk of gob workings the strata are all broken down and there is no solid stratification. In the Umpire mine that is not the case. In the Umpire mine you have simply a series of falls in the rooms, with intervening spaces of solid strata between rooms, and you would have to put a bore hole down into each room to drain the gas out from each place to be effective in the Umpire mine, because it would not go through the stratification from one room to the other into the bore holes; but, if the conditions were as in a gob working, where falls have occurred in the rooms and the pillars not extracted, then I do not think the bore hole would be of any use. From my examination of that mine at that time, I am inclined to think that there is no connection whatever, and that the stratification is not broken up in the sense that could be called gob workings, that would be of any value whatever in draining off bore holes, and that it would not be capable of draining one from the other unless there was a bore hole in each room separately.

MR. SCHELLENBERG.—As you know the gas and the oil come from coarse sands where there are cavities and where there is a connection over large areas, or reservoirs, and the pressure of the gas keeps up probably according to the head of water in those porous strata, because we find that, counting 2½ feet of water head as equal to a pound, that about balances the pressure of these walls. Where they are tighter up the gas lets go until it is shut in, and then the rock pressure goes up, but it is the quantity of gas that can pass through open stratification that governs the open pressure, and I think that this is exactly the case in the Connellsville field, which has the Redstone coal near the Pittsburg vein, so that the whole thing is connected and there is open stratification there. The indication throughout is that there is a large space over a large area to draw from for keeping up the pressure. You understand that this open rock in the gas and oil field has to be pebbly. If you have a tight rock you can get a high pressure by shutting in the gas, you can go up to 800 pounds, but an open pressure may be only 2 pounds, but if you have a pebbly rock you have a high open pressure, you have a large area to draw from. You have in Connellsville a large area to draw from for your gas. Farther down towards Pittsburg it is not quite that way, and it is only in the vein itself that we can get the pressure.

MR. KEIGHLEY.—I have known gas to come back 500 feet in less than an hour's time, especially when we first opened out. Of course, it is not so strong now.

MR. DE ARMITT.—I think Mr. Schellenberg's remarks would answer Mr. Adam's question in regard to the gas not forcing itself through the strata into the hole. In the gas hole it comes through the sands instead of the solid strata.

MR. LOUITT.—There is no comparison between Connellsville and Umpire mines. As our friend Connor says, the ribs are still in there, they may be squeezed, but the cavities are under them, and my opinion of those holes is that they are not a success all the time, because even in the Connellsville region the cavities will be under them, and there is also the possibility of gas reaching where it cannot be reached by boring because you cannot get the air to it, or the movement of the air. An examination was made of the Umpire mine from this No. 2 room up to No. 15, where the trouble is, and it was found that No. 13 is the unlucky No. 13 still, the most gas being found in No. 13, that is where the trouble began and where the explosion occurred. A bore hole there would have to be put down, I suppose, in every room.

MR. KEIGHLEY.—I believe the program has reference to gob workings.

MR. CONNOR.—I would like if the discussion would be kept to the title of this subject: "Is a bore hole a practical method of removing gas from gob workings in deep mines?" Now, if I understand what gob workings are, it is where the coal is removed entirely and the gob has taken the place of the coal. This thing of abandoned workings, where falls have occurred in rooms and the coal has been only partially excavated, are not gob workings. I have argued all along on the lines that we have gob workings, and I want to say right here and now that I do not believe that a bore hole would be of any use whatever under the conditions of the so-called gobs you have in the Upper River Pool mines, because you have not any gobs in that sense. I want to say that so-called gob workings in the Pittsburg vein, in the mines mentioned, are not really gob workings, and when they ask questions as to whether a bore hole would be effective in such mines I want to say that what are commonly called gob workings in the above locality are not properly gob workings—they are simply

abandoned workings. In a large number of their mines they make no attempt to draw pillars at all, and just as in the Umpire mine, where there are a series of falls, with intervening spaces of solid stratification between, which extends over a very great area, they have simply a squeeze right there in that hill, and those bridges, or whatever you may choose to call them, are intervening, and what you call gob workings are simply abandoned workings. Now the proposition here is for the removing of gas from gob workings from which the coal has been extracted and the roof has been broken, and I want to say that I do not believe a bore hole would be of any service whatever in mines where the pillars have been left in and these squeezes have occurred, and the facts here presented only occur where you do have gob workings and the connection is such that the gases can get over an extended area of even 16 acres, where the coal has been extracted.

MR. SCHELLENBERG.—That is, there has to be a reservoir of gas?
MR. CONNOR.—Yes, that is the case.

SIGNAL-DEVICE FOR MINES.

An Arrangement to be Used in Connection With Bell-Signal Apparatus to Ensure Ease and Accuracy of Operation.

By C. S. Herzog, Virginia, Minn.*

Some time ago, in Mexico, our signal-bells in a 700-foot shaft caused us considerable annoyance by continually getting out of order, each time so delaying our hoisting operations that we naturally desired to remedy this evil. There were two ways open: either to patch up the old bell, which was of the ordinary pattern, every time it failed to work, or else to devise some new arrangement. On consultation with our foreman we designed a signal-device which, during the number of months I watched its operation, worked satisfactorily, without once getting out of order.

We sought to produce a simple device, in which no greater pull on the lever would be necessary from one level than from another; to counterbalance independently the weight of the pendant bell-rope, so that there would be no direct weight on the working-parts of the bell itself, and likewise to arrange it so as to necessitate only a light pull on the lever in signaling; and, finally, to make some sort of trip-arrangement, so that whenever the signaling-lever underground passed through a certain arc the signal would be given in the engine-room. By this means we wished to obviate the ill effects of sudden heavy pulls and rough usage in general, such as all signaling systems encounter underground at the hands of careless or mischievous employees.

The bell-rope we had in use was a galvanized iron rope $\frac{7}{32}$ inch in diameter; and, after determining the length needed,

further end, resting on a similar surface b on B . A cross-section through xy is shown in Fig. 3.

B is a piece of flat spring-steel about 8 inches long, at the end of which is the bearing surface b . D serves as a hub, to which B and C are attached; C being a flat spring similar to B , but about 12 to 14 inches long, at the end of which is the knocker E . It should be observed that B is vertical, whereas C lies flat, and that C should not be as heavy a spring as B .

When the bell-rope is pulled to signal the engineer, the wire W moves in the direction of the arrow, and the arm a traveling downward in a circular path, around f as a center, forces b to move downward around D as a center, until the arcs in which they are traveling diverge far enough for gravity to carry $B-C$

back again to its normal position, B being arrested by the stop S ; however, the force with which the arm flies back causes the knocker to strike the gong, and thus give the signal. As soon as the bell-rope is released the arm A is carried back to its original position, and in so doing the triangular surface on the end of a slides upon the inverted triangle b (see Fig. 4), forcing it to one side (see Fig. 5), until a rests in its normal position on top of b , when it is ready for another pull, as shown in Fig. 3.

In counterbalancing the weight of the pendant bell-rope, sufficient weight must be added to the counterbalance to bring the levers underground back into position automatically. The counterweight may be located at any convenient place on the head-frame, providing it is above the bell-crank to which W is attached.

In order to prevent the pull necessary for signaling from becoming excessive, it is desirable to reduce friction as much as possible. A force equivalent to a 10-pound weight should be sufficient for pulling the levers in a well-arranged signaling-system. To accomplish this, I think it advisable to bring a bell-rope into proper alignment by means of plumb-lines, and to hold the rope in position by short pieces of old iron pipe 2 to 3 inches long, instead of by means of staples, as is so commonly done. In inclined shafts the bell-rope should be supported at frequent intervals on some form of roller. The spools on which connecting-wire comes make good rollers, in the absence of anything better.

That there may be no mistake, the arm C should be long enough, and the knocker E heavy enough to cause their instant return to position when the paths of a and b part company. For this purpose it is also advisable to put a stop, S_1 , below B , so that by no possible chance can it fly beyond its balance-point.

By increasing or diminishing the bearing of the triangles a and b , the arc traveled can be changed. In my opinion it is not advisable to increase this bearing above the inch mentioned before. The triangles, as shown in section, Fig. 3, should have bases of about $\frac{3}{4}$ inch, with perpendiculars of $\frac{1}{2}$ inch to 1 inch. The bearings of the two points f and d should be good ones, so that there will be no lateral motion, which might make a fail to engage properly with b . Any play at d or f is considerably magnified at the triangles; but by making the bases of these triangles large enough, the chances of their not working properly are greatly lessened. By moving the position of h with respect to the center f , the arc of pull underground necessary to signal, can be regulated.

The spring B must be quite stiff and of good material; but it must be borne in mind that the stiffer the spring the heavier must be the weight w_1 , and, in consequence, the greater the effort required to pull the levers; nevertheless, w_1 must be heavy enough to bring back the wire W and to overcome the resistance of the spring B . If the arm A is made sufficiently heavy, the use of a counterweight (w_1) may be dispensed with, although it is preferable to arrange as shown in Fig. 2; for by this means it can be properly adjusted. If w_1 is too heavy, the arm A has a tendency to pound against the stop S_1 . While w_1 must not be too heavy, its weight must not be cut down to such an extent as to impair the instant return to position of the arm A .

The whole apparatus may be mounted on a board and placed at some convenient spot in the engine-room.

we calculated its weight, so that we might be able to counterbalance it properly. On locating the bell in the engine-room a wire W is led off horizontally, and, by means of a bell-crank, is connected to the main signal-rope M passing down the shaft (see Fig. 1). The weight w_1 counterbalances M , and should be heavy enough to carry the wires back to a normal position, therefore it must be equivalent to the weight of the pendant rope M , plus a factor to overcome friction.

The working parts of the bell itself are shown in Fig. 2. A is a weighted lever, to the upper end of which the connecting wire W is attached; the arm a projecting from it is made of steel, about 5 inches long, and has a bearing-surface of 1 inch at its

IOWA EXAMINATIONS.

THE Legislature of the State of Iowa on March 17, 1900, passed a Bill requiring the examination of mine foremen, pit bosses, and hoisting engineers. The mining interests of Iowa are not such as to cause her to rank foremost among the mining states, but in point of intelligence she stands we believe second on the records of the last census. It is to her credit as a mining state, that she has thus recognized the necessity of such legislation and the advantage accruing from a law requiring that officials charged with the responsibility of mining work, and to whose care and intelligence is intrusted the welfare of so large a number of men, should hold certificates of competency permitting them to discharge the duties of their office.

These examinations in Iowa are to be conducted by the examining board appointed by the Governor for the purpose of examining candidates for the office of mine inspector. The personnel of the present board of examiners is as follows: Floyd Davis, Des Moines, president; James E. Stout, Des Moines, secretary; Alex. Dargavell, Centerville; John Owens, Beacon; J. W. Lewis, Hiteman. At a meeting of the Board held in July, it was decided to hold the first examination under the new law at Albia, on August 6th and 7th for hoisting engineers, and August 8th and 9th, for mine foremen and pit bosses.

There is naturally more or less anxiety about the first examination under a new law, particularly where so large a number of persons are affected. Many of the men who are at present filling positions as mine foremen, pit bosses, and hoisting engineers and who have for a long period served in such capacity, have not the knowledge that would enable them easily to pass an examination in regard to the technical points connected with their several duties. Many are practical mechanics, conscientious and careful in the performance of their duties, and the new law in some individual cases might seem at first sight to throw an unnecessary burden on them when it requires them to be examined. It is undoubtedly true, however, that technical knowledge in regard to any line of duties, renders men more capable and thorough. Such knowledge gives them a broader and more discriminating judgment, and makes their opinions and calculations more intelligent, and their service more trustworthy. While it is true that many men who have served in an official capacity for a long period of time, but who have not a technical knowledge in reference to the details of their work, often prove of greater value and reliability than others who possess technical knowledge but who have no practical training; yet on the other hand it will not be denied for a moment that technical knowledge when possessed by the practical man renders him more efficient and capable. The need of this technical knowledge is becoming more and more recognized every day by practical tradesmen of every class, and the tendency is at the present time, to fill all of the more responsible positions, especially those to which are intrusted the lives of men, with competent certificated officials.

The Iowa law allows men holding these positions in Iowa, until January 1, 1901, to provide themselves with a certificate of competency from the examining board. The law does not affect men in charge of such work at mines whose output does not exceed 25 tons. The law also provides for the granting of a certificate of competency "To any person who shall produce satisfactory evidence that he has for a period of four consecutive years immediately preceding the examination, continuously and capably performed the duties of mine foreman, pit boss, or hoisting engineer, as the case may be." This provision for a service certificate to be granted to such as had performed the duties of their office for a period of four consecutive years immediately preceding the examination, was deemed advisable in order that many practical and reliable foremen and engineers should not be rendered ineligible to an office which they had filled satisfactorily for such period, simply because they lacked a technical knowledge of their duties. In the revision of the Bill as it was

originally presented, Section 1 was altered to apply to mines having a daily output in excess of 25 tons instead of 10 tons, and the following clause was added to the section:

"But in case of the discharge, resignation, or disability of any person lawfully performing such duties, the owner, agent, operator, or managing officer of said mine shall have a reasonable time within which to secure the services of a certificated person to take the place of the one so discharged, resigned, or disabled, and during such time a competent and capable person, whether certificated as provided in this act or not, may be temporarily employed to perform such services."

Section 3 was also altered to provide for the expenses of the Examining Board, and the latter clause of the section made to read as follows:

"The members of said board shall receive the sum of five dollars per day for every day actually employed in the discharge of the duties imposed herein, together with their actual expense incurred in the performance of such duties, which expenses shall be itemized and verified as provided by section 2480 of the code, but they shall not be allowed compensation for more than seventy days in any one year."

We have received many letters from Iowa since the passage of this law, asking for information in regard to the probable character of the examination, and where and when such examination will be held; also asking for advice in reference to the preparation necessary for the examination. The examination will probably be largely of an oral nature, and be made as practical as it is possible to make it. We have recently talked with several members of the examining board, who have expressed the desire and intention of rendering the examination as practical, simple, and direct as possible. They recognize that if a difficult examination were to be presented at this early date and with the short time given the candidates for preparation, considerable confusion and embarrassment might arise. Men whose experience in mining and in the operation of hoisting engines would warrant their employment in these capacities, could satisfactorily pass a thorough, practical examination in regard to the operation of mines and of hoisting engines, etc., who would not be able at the present time to perform the several calculations required in a technical examination in regard to these subjects. We think we are, therefore, safe in saying that the judgment of the board will insure a fair and thorough examination on a practical basis. In regard to the best manner of preparation for the examination we know of no better way than for all mine foremen, hoisting engineers, and other men connected with mining, who desire to pass such an examination, to employ their spare time in the study of such questions as are regularly propounded by examining boards. For many years it has been the custom of MINES AND MINERALS to publish the questions asked in the examinations conducted in the several States and to give to each question the best and most complete answer we are able. These questions and answers are published each month in the department "Examination Questions Answered" and we believe a careful study, from month to month, of these questions and answers will best prepare men for similar examinations, as they show the character of the questions which are being asked. In this same department, there are also special short articles which bear upon these questions and which explain more thoroughly than it is advisable to give in the direct answers, the principles involved in the questions, or the method of calculation of the examples. It is the aim to make these articles as practical and valuable as possible to men who are preparing themselves for examination.

The adoption by the State of such law is evidence of the growing appreciation of and necessity for technically trained and educated men. While the examinations for a few years will probably be comparatively simple and largely of a practical nature, if we can judge from the experience in other states where similar examinations have been held for a number of years past, it is safe to predict that these examinations will gradually become more difficult and that it will require more technical knowledge to pass them. It would, therefore, be the part of wisdom for all those who are looking forward to holding such positions in the future to at once begin to prepare themselves by adopting a regular and

systematic course of reading and study. MINES AND MINERALS is desirous of assisting its readers in all such matters in every way possible and it will in future, as in the past be always ready to advise and counsel with any one who writes for such assistance.

TRUE FISSURE VEINS.

NO term in the entire vocabulary of mining and metallurgy has probably been more abused nor more unworthily used than has "True Fissure Vein," unless it be that kindred and equally overworked and abused expression "Increasing Richness with Depth."

Prospectuses without number have used and are using "the true fissure vein" as a bait and as the open sesame to the guileless investor's pocket.

A number of very reputable eastern dailies have during the past year contained glowing prospectuses and advertisements of zinc propositions in the southwest, with the Joplin District, Mo., of course, as the center. These prospectuses have laid great stress upon the true fissure character of the deposits underlying the prospectused properties. To the mining man this is, of course, a ludicrous absurdity, and it is difficult to imagine anything much further removed from a true fissure vein than a Missouri zinc deposit. To the tenderfoot investor, however, the promise of zinc ore of the quality found comparatively near the surface in Missouri, extending to the depth of the great fissure veins of the Rocky Mountains, is a most alluring prospect.

As commonly understood and as the prospectuses wish it understood "a true fissure vein" is a mineralized cavity in the earth's crust extending to a considerable depth below the surface. The vein stone carries the pay ore and this may or may not continue with depth. As far as depth is concerned, it is by no means settled that fissure veins extend any deeper into the earth's crust than do bedded deposits, pipe veins, or contact veins, and even if they do extend to indefinite depths this is of little value, as the limits of economical mining are reached at comparatively shallow depths. A report or a prospectus which figures on deposits of unlimited depth is simply playing on the ignorance of the investor.

The fact that many of the fissure veins of the Rocky Mountains and Pacific Coast regions have contained rich deposits of precious metals has made this term "true fissure vein" an easy one to be used on the unwary. There is a very alluring ring to the sound of the words and they make a most eloquent text for the promoter. The investing public is easily intoxicated by a few doses of true fissures. A practical miner also readily grasps hold of a true fissure vein, and the first ring of his pick satisfies him that he has the genuine article and that it has its tap roots in the antipodes.

Properly used, the term "true fissure" is useful and very descriptive but where used as an incantation to call up visions of wealth extending to unlimited depths it needs suppressing.

OILS AND OILS.

WE have reason to believe there is a very common and popular delusion regarding oils. A man thinks when oil signs appear on his farm or when he has bored and actually struck oil that he has struck something of great value. There are oils and oils; there are some, and these far in the majority, that are of little commercial value, being too heavy for illuminating purposes and only good for second-class lubricating purposes, for which there is only a comparatively small market.

In Colorado, while there are numerous localities known to carry oil, there is but one, viz., that of Florence, which contains oil of sufficient lightness to be of valuable illuminating quality. The horizon in which oil occurs in Colorado, so far as at present discovered, is mainly in the shales of the Marine Cretaceous. This is a widespread and very thick formation occurring nearly all along the flanks of the Rocky Mountain range and in the parks of Colorado. The same formation also carries the heavy oils of

Wyoming. There is no reason why locally this formation, under favorable conditions, should not carry the valuable light illuminating oil in other places besides at Florence, but so far such has not been discovered.

The chemical conditions for an illuminating oil require a specific gravity of 30 to 45 Beaumé or an ordinary specific gravity of .8750 or .8000. These will give the following percentage of illuminating refined oil:

Beaumé.	Specific Gravity.	Per Cent. Oil.
30	.8750	30
45	.8000	75

The eastern oils have, we believe, from 40 to 44 Beaumé.

It is well then, for any one who thinks he has, or really has, oil signs on his land to consider these conditions and have the oil-show analyzed before he begins costly experiments. Oil must have a good paraffin base, not an asphaltic base, as quite a number have. It must be a light oil and not a heavy oil. Some heavy oils may carry a small percentage of good illuminating oil, which might be extracted from the crude, but the expense involved, with the amount of refuse material, is liable to eat up all profits from the refined.

BOOK REVIEW.

BULLETIN OF THE UNIVERSITY OF THE STATE OF MISSOURI, Columbia, Mo. Vol. 1, No. 3.

TRANSACTIONS OF THE NEW SOUTH WALES CHAMBER OF MINES, SYDNEY, N. S. W. Vol. 1, No. 2, May, 1900.

THE INDIKIL SYSTEM. A decimal system of weights and measures for the English speaking people, by A. Lincoln Hyde, Cleveland, O., 1900. 13 pages.

THE CRIPPLE CREEK VOLCANO, by T. A. Rickard. A paper read before the American Institute of Mining Engineers at the Washington meeting, February, 1900. 37 pages.

TWENTIETH ANNUAL REPORT OF THE AGRICULTURAL EXPERIMENT STATIONS OF THE LOUISIANA STATE UNIVERSITY AND A. & M. COLLEGE, FOR 1899, TO THE GOVERNOR, BATON ROUGE, LA.

BULLETIN NO. 3 ISSUED BY THE TERRITORIAL BUREAU OF IMMIGRATION FOR NEW MEXICO, ALBUQUERQUE, N. M. Pamphlet 23 pages. This pamphlet presents brief accounts of the principal mining regions of New Mexico.

BULLETIN OF THE AGRICULTURAL EXPERIMENT STATION OF THE LOUISIANA STATE UNIVERSITY AND A. & M. COLLEGE, BATON ROUGE, LA. Second Series, No. 60. "Charbon, Further Investigation and Suggestions, with Summary and Conclusions."

PAPERS READ BEFORE THE INSTITUTION OF MINING AND METALLURGY AT THE GEOLOGICAL MUSEUM, S. W., JUNE 20TH, 1900. "On the Extraction of Gold from Auriferous Pyrites by Amalgamation," by Thos. G. Davey; "The Treatment of West Australian Sulphide Ores," by Alfred James; "Notes on Gold-Bearing Gravels," by W. S. Welton.

NUMEROUS IMPROVEMENTS were brought about by the activity of the Department of Mines during 1899 in connection with ventilation and similar problems which have become prominent in connection with the increasing depth of Australasian mines. Seven mines are now working in the Bendigo District, varying in depth from 3,000 to 3,424 feet.

CAHALL WATER-TUBE STEAM BOILERS, manufactured by Aultman & Taylor Machinery Co., Mansfield, Ohio. Although nominally a catalogue, this is another of those engineering textbooks for which the profession is indebted to the manufacturers, for in addition to the part which particularly describes the Cahall boilers there is much general information which will be found useful to all engineers.

PROCEEDINGS AND COLLECTIONS OF THE WYOMING HISTORICAL AND GEOLOGICAL SOCIETY, WILKES-BARRE, PA. Rev. Horace Hayden, Secretary. In addition to the strictly historical articles this report contains an interesting article on the Drift Mounds of the Susquehanna Valley and a catalogue of the Lacoe collection of fossils which are now deposited in the rooms of the Wyoming Historical and Geological Society.

PRODUCTION OF THE PRECIOUS STONES IN THE UNITED STATES IN 1899, by George F. Kunz. Extract from the 21st Annual Report of the United States Geological Survey, Washington, D. C. Pamphlet 48 pages. This report like all of the preceding ones by Mr. Kunz on this same subject is most complete and interesting and well worth the reading by any one interested in the mineral resources of the United States. Over one-third of the report is devoted to the discussion of the diamond, and another third

to corundum gems. The other gems are treated briefly. The value of the production of precious stones in the United States during 1899 was \$185,770. The growth of this industry is shown by the fact that in 1896 the value was \$97,850; 1897, \$130,675; and in 1898, \$160,720.

ANNUAL REPORT OF THE MINISTER OF MINES OF BRITISH COLUMBIA FOR THE YEAR 1899. 890 pages profusely illustrated. Published in Victoria, B. C. Price 50 cents. In addition to the general statistics of British Columbia this report contains detailed descriptions from the several sections, together with accounts of a number of well known mining properties. The typographical appearance of the book is most pleasing and British Columbia is to be congratulated upon so excellent a report setting forth the advantages and resources of her mineral products.

ANNUAL REPORT OF THE SECRETARY OF MINES AND WATER SUPPLY FOR VICTORIA, AUSTRALIA, FOR 1899. Melbourne, Australia. 78 pages. During the year the gold output in Victoria amounted to 854,500 oz., an increase of 17,243 oz. over the preceding year. The total production of Victoria to date amounts to 63,539,205 oz. valued at £254,156,820. The gold yield of the Australasian colonies during 1899 was 4,463,116 oz. worth £16,180,723. The increase in production since 1895 has been remarkable and amounts to 2,114,150 oz. Since the discovery of gold in 1851 the Australasian colonies have produced 110,413,597 oz. of gold valued at £427,194,079; 60% of which has come from Victoria. The best dividend paying mine in Victoria yields an average of 38 dwt. 11 gr. per ton, but a mine which yields one 1 dwt., 21 gr. pays dividends.

REVIEW OF THE AMERICAN STANDARD SPECIFICATIONS, Test Pieces, and Methods of Testing Iron and Steel adopted by Committee No. 1 of American Section of the International Association for Testing Material, by Albert Ladd Colby, South Bethlehem, Pa. Pamphlet 100 pages. A paper read before the International Association for Testing Materials, Paris, France. The full scope of the paper is given by the following chapter headings: (1) Review of the American standard specifications, test pieces, and methods of testing iron and steel; (2) The actual every-day practice of American steel works in determining the physical properties of iron and steel; (3) Methods in use in American steel works for the chemical analysis of steel; (4) Critical review of foreign specifications for steel rails; (5) Appendix containing the full text of the specifications for steel and wrought iron adopted by Committee No. 1, of the American Section of International Association for Testing Materials, May 1, 1900.

PERSONALS.

Mr. C. O. Brunner, treasurer of the Bethlehem Iron Company and Bethlehem Steel Company, completed on July 12th his fortieth year of service. The occasion was marked by the presentation to Mr. Brunner of a silver pitcher and salver and a handsome cane from his fellow members of the staff of the two companies.

The Naval Electric Company, with offices at 95 Liberty Street, New York City, has been organized to succeed the B. & H. Electric Company, of Dansville, N. Y., and New Haven, Conn. The same officers continue, the change in name being made as more appropriate for the distinctive line of electrical business in which the company proposes to engage. F. G. Hall, Jr., A. S. M. E., is the manager for the company, and I. E. Burdick, secretary and treasurer.

The Chicago Pneumatic Tool Company has engaged Mr. Fred. F. Bennett as sales agent and manager of advertising, with headquarters at the main office of the company, Monadnock Block, Chicago. Mr. Bennett, who resigned a position as sales agent for the American Steel Casting Company and American Coupler Company, of Chester, Pa., July 1, has had long experience in the journalistic field, has a wide railroad acquaintance, and has a thorough knowledge of trade publications.

Siberia's Mineral Resources.

Siberia produces one-tenth of the world's yield of gold, and but few of the mines have been worked, on account of the climate. The immense coal deposits have hardly been touched. One mine, with six beds, contains as much coal as all the deposits in England. The lack of transportation facilities alone has prevented it from being worked.

The Trans-Siberian Railroad, from an economic and a political standpoint, is the greatest work of this century. It gives Russia a superior standing in Pekin. It now touches the Amur; in three years it will reach Port Arthur, making the distance but thirteen or fourteen days from Moscow to Pekin.—U. S. Consular Reports.

CORRESPONDENCE.

This Department is intended for the use of those who wish to express their views, or ask or answer questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided. All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith. The editor is not responsible for views expressed by correspondents in this Department. Correspondence should be in as simple language, and as free from technical terms and formulas as possible, consistent with clear solution. Questions on subjects not directly connected with mining will not be published.

Sulphide of Arsenic.

Editor Mines and Minerals:

SIR:—Will you kindly give me whatever information you can as to the uses and the amounts consumed of sulphide of arsenic (realgar). Kindly give me a list of the principal users and dealers in this mineral. Also please give me a list of the best work or works on the treatment of arsenic ores. Yours truly,
510 South L. St., Tacoma, Wash. F. H. WHITING.

Mensuration.

Editor Mines and Minerals:

SIR:—If a board is 12 ft. long and 12 inches wide at the big end and tapers from both sides to a point, I would like to know where it should be sawed across so as to have an equal amount of timber in each end. Yours, etc.,
Quincy Mine, Park City, Utah. I. C. HARRINGTON.

Locating Mineral Claims.

Editor Mines and Minerals:

SIR:—Will you kindly tell me whether mineral claims can be located in Minnesota, Michigan, Missouri, and the other Mississippi Valley States the same as in the Rocky Mountain States. If this cannot be done please state why this is so. Yours truly,
Red River, Minn. S. H.

The United States mining laws are not in force in any of the thirteen original States, nor in the States of Vermont, Tennessee, Michigan, Wisconsin, Minnesota, Missouri, Kansas, Alabama, Kentucky, or Texas, nor in Oklahoma or the Indian Territory. Valuable mineral deposits in lands belonging to the United States, in any of the States or Territories other than those above referred to are subject to disposal under the United States mining laws. It has been decided that a homestead entry would not be defeated by the discovery of a valuable deposit of mineral on the land covered thereby, provided the discovery was made subsequent to the issuance of the final certificate.

Monte Cristo District, Washington.

Editor Mines and Minerals:

SIR:—The Monte Cristo mining district, which is about to be reopened through the rebuilding of the Everett & Monte Cristo Railroad, will no doubt be of interest to many of our readers. This district was opened during the years of 1891-2, during which time the Rockefeller interests expended some five or six hundred thousand dollars in putting their properties here in shape to ship ore. In connection with their mines here they built the Everett & Monte Cristo Railroad, which connected their mines with their smelter at Everett, Wash. During a heavy mountain flood in 1897 the railroad was washed out and has remained so until the present time, but now the same is being rebuilt. Yours truly,
Monte Cristo, Wash. B. NORBERT OUMETTE.

Ventilating Air-Shaft.

Editor Mines and Minerals:

SIR:—A tunnel is 3,000 feet in length. Would an air shaft 1,400 feet from the mouth and 6 inches in diameter be large enough to ventilate it? Length of air shaft, 400 feet; formation of rock, gneiss. If the above would not be of sufficient size, how large should it be? Yours truly,
Idaho Springs, Col. JAMES UNDERHILL.

It is difficult to understand the meaning of this question. Does Mr. Underhill mean to ask if the ventilation of the tunnel can be accomplished by blowing air through a 6-inch bore hole? This can be done if the quantity of air required is small and an air pipe is used to conduct the air forward to the face of the tunnel where it is needed. It may be, however, that the reading "6 inches" is an error, and the question should be read

"6 feet" as the diameter of the air shaft. In this case, the ventilation of the tunnel is merely a matter of how much air is required, and the establishment of the ventilator that will supply this amount.

Gold Refiner's Problem.

Editor Mines and Minerals:

SIR:—Replying to Gold Refiner's problem in the March issue of MINES AND MINERALS.

Let d = difference in fineness between bullion to be added and fineness of bullion sought;

D = difference of bar in hand and fineness of bullion required, multiplied by weight of bar in hand;

W = weight of bullion to be added.

Then,
$$\frac{D}{d} = W.$$

According to problem, first part, $1,000 - 500 = d = 500.$

$32.3 (500 - 462) = D = 1,227.4.$ $\frac{1,227.4}{500} = 2.4548$ ounces, 1,000 fine to be added.

Second part, $900 - 500 = 400 = d.$ $32.3 (500 - 462) = 1,227.4 = D.$ $\frac{1,227.4}{400} = 3.0685$ ounces, 900 fine to be added.

Yours truly,
Nelson, B. C. A. L. McK.

Prospecting.

Editor Mines and Minerals:

SIR:—Will some prospector please give his experience regarding the following: While prospecting with pan on the hillside I obtained gold quite frequently near the base of the hill. In going higher the colors got smaller and fewer until finally I could get only a trace of gold. A few yards farther up the hill the formation changes from a highly ferruginous and decomposed slate to a more argillaceous and firmer variety. Between the two appear to lie several feet of a solid tough clay, which may be a decomposed porphyry. The soil is quite deep. There is little quartz attached to the gold. According to your experience would you expect a vein of some kind near this contact? Is it a general occurrence for gold to become less abundant near the outcrop of its source? If so, how do you account for this? Do you know of any veins of value having been found where the gold below their outcrop occurred only sparingly? I have spoken to others about this matter but have been unable to receive a satisfactory answer. Yours truly,
Covelo, Cal. PROSPECTOR.

It would not be unlikely that the porphyry itself might have the gold-bearing vein in contact with one side or the other of it, or that there might be one in its immediate vicinity, also the gold may be extremely "pockety" and hence require considerable search to find any of it in place. Concerning the occurrence of more gold near the base of the hill, this could be accounted for in some cases by the fact that as the talus or other material slid down the hill it would carry the gold with it. Subsequent erosion might wash and remove more material from the foot of the hill than from other points higher up, owing to the fact that the greater volume of water would be in motion at these places and at a greater velocity. This larger volume of water would disintegrate the talus, wash away the fine gold and much of the earthy matter, leaving only the coarse gold, while higher up the hill the fine gold may occur. It is impossible to give any more exact statement as all the facts are not fully stated, but I should first look for a vein near the porphyry, and, if not found, it would be well to then investigate the origin of the soil and try and determine whether it was of local origin or was composed of drift stuff brought from some distance.

Drainage and Pumping in Mines.

Editor Mines and Minerals:

SIR:—The article published in MINES AND MINERALS for May 1900 on "Drainage and Pumping in Mines," contains several good and useful suggestions. But from the standpoint of my little practical philosophy the latter part is erroneous and very misleading; especially so to the young student. I quote from the article as follows: "In determining the head of water under which the pump must work and against which it makes its discharge, it is customary to measure the vertical height from the pump to the point of discharge; the pressure due to the head of water is easily calculated by multiplying by .434." etc.

The above statement is certainly misleading as it costs the same mechanical labor and power per foot of vertical height from the pumping machine, to elevate water from its source or sump to the pump, as it does from the pump to the discharge point; consequently if an engineer should make a calculation according

to the quoted instructions on a pump for a twenty-five foot vertical height from source of water to pump, and twenty-five foot vertical lift from pump to point of discharge, he would find himself with half the necessary power to do the work.

Finding diverse opinions on the quoted statement, I referred it to the acknowledged authority on mine affairs in our district, and was told that the statement was correct; that the water comes to the pump from the sump on the principle of a siphon, and at no cost of power to the pumping machine. Again I referred it to two able and prominent candidates for the mine inspectorship, and for my trouble received some very uncomplimentary remarks about my knowledge of the textbook, etc., but after considerable discussion and pencil drawing, they agreed to look up the question. I also recollect a discussion carried on for several months in regard to this principle in the Correspondence pages of the Colliery Engineer about eight years ago, when I wrote a few lines which seemed to have closed the discussion; but I have been unable to find these few lines and would be obliged if you could refer to them and also give us some definite views on the question under consideration. Very truly yours,

Pittston, Pa.

D. W. E.

[We are glad to have our correspondent draw attention to the above. The reference to "the head of water under which the pump must work," as made in that article, was a general statement in which the pump was considered to be practically at the bottom of the lift, and the head under which the pump works is there spoken of, in a general way, as being the height from the pump to the point of discharge. Our correspondent is right, however, in saying that this height is the difference between the level of the water in the sump and the point of discharge, and the statement made in regard to the head of water should so read. It did not occur to us that there was any danger of some one's misunderstanding what was meant, or to what the head (*h*) was intended to refer, as we had in mind at the time, more particularly, a pump located at the bottom of a deep shaft and drawing its water from a sump practically at the level of the pump, which is true in regard to the location of mine pumps, in the majority of cases.

In regard to the question as to whether the vertical height from the level of the water in the sump to the pump, should be added to the height of the discharge above the pump, we would say it should by all means be so added. The effective head under which any pump acts, as previously stated, is the vertical height of the point of discharge above the level of the water in the sump. The pump elevates the water from the sump to the pump just as truly as it does from the pump to the point of discharge. The fact that a depression is caused behind the piston of the pump as it makes each stroke backward and forward, and that the atmospheric pressure acting upon the surface of the water in the sump, presses the water up the suction pipe and into the pump, does not alter the conditions as far as concerns the pressure head under which the pump works.

When the pump is located at the level of the sump and there is practically no suction head, the atmospheric pressure acts likewise upon the piston of the pump and the point of discharge, and the effective head is then simply the head of water-column from the pump to the point of discharge. If, however, the pump is located above the level of the water in the sump, the atmospheric pressure upon the piston of the pump is decreased by the suction head, and it is then very clear that the effective head under which the pump performs its work, is increased exactly by this amount, since the effective head upon the pump is the difference between the pressures upon the pump piston and the point of discharge. In locating the pump above the sump level we decrease the atmospheric pressure upon the pump piston and thereby increase the effective head upon the pump, and this increase is exactly the suction head.

There is no siphonage, in this case, whatever, and we think, perhaps, that our correspondent did not make himself clearly understood to the men to whom he referred his question. The discussion referred to by our correspondent arose from a question asked by "Beginner" in the Correspondence columns of The Colliery Engineer, Page 8, August, 1891, and continued in succeeding issues till the question was finally answered by our correspondent on Page 128, January, 1892.—Editor.]

Preparation of Anthracite.

Editor Mines and Minerals:

SIR:—There is a subject that, I think would be appreciated by all the anthracite mining boys, viz. the peripheral velocities of revolving breaker screens. In all my readings of the MINES AND MINERALS I have no recollection of ever seeing anything appear on this subject. I would therefore be indebted to you if you can find time to give us an article on this line, or if preferable to make some remarks upon the following formula, and numerous other facts that I have observed:

Let us take a two-circled screen, 5 and 7 feet diameters respectively, and perfectly horizontal, now let some coal drop into the bottom of the 5 ft. circle at *E* for a short interval, and then stop feeding. What velocity of periphery speed must the screen travel so that the coal at *E* will continue to go around with the jacket without falling back to the bottom center of the screen at *E*? We find that the force of gravity at the equator is equal to 16.1 ft. fall in one second of time, or, for the sake of our illustration with the 5 ft. screen we will say 16.2 ft., hence, when centrifugal force is equal to centripetal force (16.2) we have $g = \frac{C^2}{D}$, g being the power of gravity, D the diameter of the screen, and C the peripheral velocity per second.

To answer our question, then, taking the 5 ft. diameter screen, we have $\sqrt{16.2 \times 5} = 9$ ft. per second, for $gD = C^2$; this then is the velocity required with any material, when it cannot slide back, or down over the meshes to the bottom of the screen. If this is true, what should be the utmost peripheral velocity, so as to lift the coal to a certain distance, so that gravity may act upon it and draw it back down over the mesh to be rescreened.

Again, what relation is there, if any, between the peripheral velocity and the amount of pitch given to the screen? Take the 5 ft. and 7 ft. diameters as shown, should the velocity of the screen's periphery be made as high as to exceed the length of the chord of 90° *E F* and *C B*, or equal to the arcs *E G F* and *C D B*, or should it exceed the chord of 60° *E G* and *C D* and their arcs? The chord of 90° for a five foot diameter screen = $\sqrt{2.5^2 + 2.5^2} = 3.53$ ft., and the arc of said quadrant = $3.1416 \times 5 \div 4 = 3.93$ ft., and for a 7' diameter screen, the chord of 90° = $\sqrt{3.5^2 + 3.5^2} = 4.95$ feet, nearly, and the length of the arc = $3.1416 \times 7 \div 4 = 5.49$ ft. In observing the velocities of screens in various breakers that I have visited I find quite a difference, and especially so between old and new breakers.

The following are some screens that I know to give good satisfaction in sizing their coal: Here is a 7 ft. diameter screen running chestnut over mesh, and dropping through pea, buck, rice, and culm, and traveling at the rate of 5 ft. periphery speed per second, developing a centrifugal force of 3.57 ft. Another 8 ft. diameter screen has 5.82 ft. periphery speed and a centrifugal force of 4.23 ft. running stove over mesh and dropping through all smaller sizes. Another is 7 ft. diameter running egg over mesh and dropping smaller sizes through, making a velocity of 6 ft. per second and a centrifugal force of 4.50 ft. I know of a screen running pea over mesh that when the velocity was increased from 2.09 ft. to 3.6 ft. periphery speed per second, the quantity of coal passing through also measured about one-third and all well sized. If the pitch of this screen had been increased, instead of the velocity, would the result obtained be the same, and therefore, the greater the pitch the less the speed, and vice versa?

How many tons per hour would you estimate a 7 ft. diameter screen 20 ft. long could pass through, chestnut running over 1½ inch mesh, and all other sizes below dropping through? Pitch of above mentioned screens are all = ¾" per foot?

Yours truly,

W. D. OWENS.

Pittston, Pa.

[The questions raised by Mr. Owens are very interesting practical questions and we trust they will be taken up and discussed by those interested in the preparation of coal.—EDITOR.]

Mining Notes Regarding Tatepuzco, Acuitapilco, San Bartolo, etc.

Editor Mines and Minerals:

SIR:—There are in the dumps of the mines named Mine Grande, Tajitos, and Quezadeño, located in the mining district of Tatepuzco, Ahuacatlan, Tepic, more than 600 cargass of 138 kilos each, of ore averaging from 4 ounces to 5 per carga (30 oz. silver per ton). The ore is a concentrating ore, and a 3-stamp mill with a crusher and a concentrator can easily operate during seven months of the year with waterpower, and five by a steam 10 H. P. engine.

There is an old Hacienda de Beneficio (amalgamation process) which can be repaired with a thousand dollars Mexican. The total production of the ores may be calculated as 200 cargass of 138 kilos each, in the present conditions of the mines and hacienda, but the experts who have examined the properties say that the mines may become great producers and thousands of tons may be extracted from the old tunnels and shafts which are now caved in.

The mines of Tatepuzco are of a very great expectation and

only capital and an intelligent management are required to get millions of dollars from the working of such mineral.

The mines of Acuitapilco called El Mezquite, Trinidad, Catarina, and Buenavista, and Todos Santos were worked with success by the old Spaniards and later by miners from Guadalajara. Mr. Miguel Orendain, a native from Guadalajara, got a nice fortune by working the Mezquite in 1840. It is reported that the ore was so abundant that the miners working at that time day and night were not sufficient to reduce all the ore. The ruins and workings which for the present can easily be seen by visiting the place indicate the importance of the mines. One of these mines, the Valenciana, is being developed by an American company. A 3-stamp mill, a crusher, and a concentrator will soon be in place. For the present 50 men are employed at Acuitapilco. The high grade ore is being sent to the reduction works of Messrs. Lonergan & Stanhope, and the low grade ore is being reduced by the old patio process, with success, as good returns in gold and silver are being received by the company. Mr. J. S. Ickis has assumed the control of the working and a tunnel is open which facilitates the extraction of the ore. Ten tons daily is the present extraction of the pay mineral; the formation of the district is quartzite and porphyry. Rich streaks have been encountered assaying from 600 to 3500 ounces per ton of 2000 pounds.

The owners of the mines have later acquired the rights to two waterfalls which operate the six old tahonas used in the reduction of the ores, but as the Valenciana Company will soon erect a reduction plant, the reduction of the ores will be made, giving good profits to the proprietors. The level ground is sufficient for the erection of a large reduction plant, and the waterpower is also sufficient to operate any class of machinery.

The San Bartolo mines are situated to the southeast of the City of Tepic, 15 miles distant, and 60 kilometers from the San Blas seaport on the Pacific coast. The veins are so wide that any amount of low grade gold ore, free gold and concentrating, can be had in sight. Water power can be easily had close to the mines; timber and hardwoods can be had at a very cheap price. The average of the ore is 30 ounces silver to the ton of 2000 lbs., and 10 ounces gold. The erection of a large reduction plant with many concentrators is the best investment here in this district.

On the south of San Bartolo are situated the mines of Guadalupe and San Juan; the first mine has a rich streak the ore averaging 300 oz. silver per ton and 3 oz. gold. The San Juan has any amount of low grade gold and silver ore. The present owners have ten men constantly at work exploring the district; rich stringers cross the vein and it has a width of two meters. The old mines, the celebrated mines of the Countess of Miravalles were worked by the Spaniards and millions of dollars were sent to Spain by Muño de Guzman and successors. The immense fortune of the Countess of Miravalles was made by the working of her mines. For the present the best mine, named La Concesa; has been located and a company is to be organized with the end of exploring this rich region. The Pacific States Mining and Investment Co., of San Francisco, California, will soon organize a new company with the object of exploring Tepic.

Yours, etc.,
TEPIC.

Kentucky Zinc, Lead, and Fluorspar District.

Editor Mines and Minerals:

SIR:—Much has been said of late of the remarkably rich deposits of zinc, lead, and fluorspar, as found in Livingston and Crittenden Counties, Kentucky. These deposits are found in true fissure veins, identical with those of the leading mines of the Old World and much different from those so far opened up in the United States, namely the Kansas-Missouri district, where the minerals zinc and lead are found in pockets or blankets in the limestone and where one hundred tons of rock must be removed to obtain 6 tons of zinc, for the average for the entire Kansas-Missouri district is about 6%.

The new southwestern Kentucky district has already shown such wonderful developments in zinc, lead, and fluorspar as to surprise all operators. This district, which six months ago was comparatively unknown, has in such a short period developed over two dozen producing mines; there are ten or twelve companies in the field and new ones coming daily.

The minerals as found are extraordinary from the fact that the entire vein matter is a combination of the three minerals, namely, zinc, lead, and fluorspar. In the separation of same there is about 10% of loss; the average value per ton for every ton mined is over \$22.00.

The zinc produced in this district is of a high grade assaying from 62% to 65½% metallic zinc and less than 1% iron. The lead is only equaled by that of the St. Francois district. The fluorspar as produced in this district is the only fluorspar ever found in the United States and the richest ever found in the known world; it assays from 95% to 99.86% fluoride of calcium, that of England and Germany rarely reaches 45% fluoride of calcium.

There have been some 12 or 15 of these true fissure veins opened up to date; they are well defined, having been traced from 5 to 20 miles, and are from 3 to 40 ft. wide; the depth has never been ascertained, there apparently being no bottom.

This southwestern district has many advantages over all others it being well supplied with waterways and railroads, and near the market centers. This district has proven a revelation, the supposition being that no district in the United States could ever equal those of Belgium, Spain, Italy, Wales and England for the reason they had the true fissure veins, but now Kentucky comes to the front with the same mineral formation and in addition has the fluorspar which will prove an important factor. Heretofore all the fluorspar used in the United States, amounting to millions of dollars, has been imported. The greatest portion is yet imported, developments in the southwestern Kentucky district not having reached that point where it can supply the great demand which is constantly increasing.

A very fair illustration of the progress made in this district can be drawn from the following: The Bonanza mine in sinking a shaft to 75 ft. removed 450 tons of fluorspar assaying 99.85% fluoride of calcium the richest known mine of its kind in the world.

The Morning Star mine in sinking shaft to 70 ft. removed lead and fluorspar both of superior quality from within 5 feet of surface to present depth. The Evening Star, joining the Morning Star, at 78 ft. has gone through 45 ft. of solid mineral vein which is 35 ft. wide. They have enough ore to run their mill, which works the dry process, for many years. This mill has only two duplicates in the United States.

The Columbia mine at 150 ft. has four drifts run all in the finest kind of ore. There is a mill and smelter on the property. The Hodge mine has shipped 8,000,000 lb. in eight months' work. The Rose Clare mine at 240 ft. has 2 drifts run 230 and 400 feet respectively, daily shipments of 45 tons, a fully equipped concentration mill and all improved machinery.

The Memphis, Yondale, and Tabb with mill located at Marion, Ky., on Illinois Central R. R., has 4,000 tons on dump and is making daily shipments. The Holly, La Rue, Pansy Blossom, Sweet Marie, Babb, Guill, Milner, Cox and others are in good ore.

A remarkable feature of this district is the progress made by those working. Some there are, of course, working day and night; but the results in such a short time are wonderful.

Salem, Livingston Co., Kentucky, is the center of operations. The Cumberland River is on the south and the Ohio River on the north and west, while the Illinois Central R. R. traverses the district. With mines producing mineral assaying 20% to 42% zinc, 18% to 25% lead, 30% to 50% fluorspar, and less than 10% waste in separation it is not hard to prophesy a brilliant future for the southwestern Kentucky district.

Yours, etc., E. LANGENBACK,
Vice-Prest. Berger Mfg. Co.

Canton, Ohio, July 10, 1900.

Arizona Notes.

Editor Mines and Minerals:

SIR:—Continued and increasing activity in mining seems to be the order of the day, in Arizona at least. The Little Meadows find several weeks ago has been succeeded by the opening up in the Redemptus mine near the Rainbow Group, in the Hualapai district, of a large body of rich silver ore with every prospect of its continuation. I looked this property over last fall and encouraged the owners to push the work in the tunnel in which the discovery was made in preference to sinking a winze as they contemplated. Mr. Furguson and his sons are to be congratulated; they are hardy prospectors and deserving of all they may find.

Having been called to Los Angeles on business connected with the putting in of a large plant of machinery I have taken some considerable pains to look up what might be new in the line of machinery for the economical handling of ores. In that line I found two appliances, a crusher and a muller, which deserve attention. The crusher consists essentially of a vertical plunger working in vertical ways in proximity to a stationary crushing face, which is substantially parallel with the face of the plunger at the lower end, throughout a considerable extent, and diverges from the face of the plunger at the upper portion. The plunger is adjustable from and toward the fixed jaw, in order to gauge the opening through which the crushed material will be discharged, thereby regulating the size of the crushed material. The inventor of this crusher and muller is Henry B. Case and the advantages presented to my mind by this machine are: (1) The rock is broken by chipping instead of by pinching, so that the body of the pieces of ore does not have to be crushed, but is broken around the corners and edges, and the portions thus broken away fall into a constantly narrowing space, to be again broken in like manner, and so on, until the material reaches the

narrowest space. (2) The material immediately before its discharge, has to pass through a long passage, the space between the walls of same being accurately gauged, so that the finished product is practically of a uniform size. Tests which have been made show that when the machine is set to crush to a 40 mesh size, the percentages of different ores run from 20% to 52% between the 40 and 60 mesh, showing that the percentage of slimes would be much less than is usually obtained. (3) The pulverized particles do not remain with the unpulverized material in the crusher, but immediately pass out of the discharge opening, thus preventing further pulverization when the particles have been brought to the proper size. (4) The final process of pulverization is accomplished by a rubbing motion between the two flat surfaces, so that the particles of free gold or other metals contained in the ore, are not pulverized or flattened, but are rolled into wire form, and are therefore more readily collected. The capacity and speed, from the experiments which have been made, indicate that a larger quantity of rock can be pulverized with less power than with other crushers.

The most economical plant will consist of a number of machines, the largest of which will come first and each of the other sizes following, each one being set on a lower level, and connected by a conveyor provided with the proper screens until the last one is reached and the final sizes made. The saving in original cost over stamps and other heavy crushers, and reduction in cost of transportation by reason of reduced weight will be carefully considered by mining men.

The "Telegraph" Group in Greenwood district will in the near future probably change hands and within 90 days thereafter a large cyanide plant will be at work upon the ore, of which there is by actual measurement over 260,000 tons in sight above the surface of the ground that will net the new owners from \$9.00 to \$12.00 per ton. In my next I hope to have something of especial interest to machinery men and investors in mines. Our new railroad which will pass through this section is making good progress with the grading and the surveyors have now reached the junction of Boulder and Burro Creeks.

Yours, etc.,

W. A. MENSCH.

Signal, Mohave Co., Ariz.

Taylor-White Tool Steel.

Of the many remarkable industrial developments in the United States during the past two decades none is more striking than the development of the manufacture of armor plate and heavy forgings. Fifteen years ago no work of this kind was done in the United States, but within that time new plants have been completed and the process of armor plate manufacture and the work of heavy forging have been so perfected that American firms now enter the European market and are able to compete with and secure work in opposition to European firms which have been long established.

In this development the Bethlehem Steel Co. has been particularly prominent and it has gradually developed a plant which is one of the most interesting in the world. Several years ago it was found that, although the company already had the longest machine shop in the world (more than $\frac{1}{2}$ of a mile in length), this shop could not handle all of the work being turned out by its other departments. Before building another machine shop, which would have meant an expenditure of at least a million dollars, it was decided to reorganize the shop methods which were prevailing at the time.

In the reorganization of the shop method Mr. F. W. Taylor, the well known expert in shop organization, found several changes necessary, the most important of which was the discontinuance of the miscellaneous assortment of tool steels used by the different men in the shop, and the establishment of a standard and uniform grade of tool steel, the use of which would be enforced upon all of the men regardless of their preferences.

A special lathe was set aside for the purpose of experimenting with all brands of tool steels, and under the direction of Mr. Taylor and Mr. Maunsel White, Engineer of Tests of the Bethlehem Steel Co., over 200 tons of steel forgings were cut up into turnings. Out of this exhaustive investigation there was gradually evolved, after an expenditure of over \$100,000 in labor and material alone, the "Taylor-White process." The details of this process have not yet been made public as the patents are still pending, but it is understood to be a special heat treatment of a peculiar brand of self-hardening tool steel. Although large sums have been spent in developing the apparatus, the appliances for carrying on the process as now used are said to be extremely simple and to cost only \$600. It is automatic in action so that it does not require skilled labor in carrying it out. The process is applied after the tool has been dressed to shape and the effects of the treatment penetrate throughout the steel and are not simply on the surface. The process has been applied to a number of standard tool steels

and the efficiency of a Mushet tool steel can be increased 25%, but the best results are obtained from a special composition of steel.

The Taylor-White process steel has the valuable and exceptional quality of retaining a high degree of hardness at a red heat and it is possible with tools made of it to cut at a speed great enough to heat the point of the tool to redness. Cutting with a tool thus heated leaves an unusually smooth finish on the work, thus greatly decreasing the work of finishing. This special steel forges readily so that tools of difficult and irregular shapes can be made from it. A simple, rapid method of annealing the steel has also been found by which tools may be easily machined to shape, making it applicable to twist drills, chasers, inserted cutters, etc., heretofore never made from self-hardening steel. Owing to the automatic feature of the process the steel obtained is very uniform in product and the variation in quality of the tools is said to be not over 5%.

The Taylor-White tools can be run from 2 to 4 times as fast as any other tools on the market. A great advantage in the use of these tools is that when cutting dry at the rate of maximum efficiency the chips should come off blue, these blue chips enable a foreman at a glance to tell whether the work is being done at the proper speed. When running under water at the proper cutting speed the chips should show blue immediately upon shutting off the water and allowing the tool to cut dry for a few moments.

The Bethlehem Steel Co. through its introduction of this tool steel into its machine shop has completely solved the problem which it undertook two years ago and now the capacity of the forge has to be greatly increased to keep pace with the growing efficiency of the machine shop in which the speed of the main line shafting has been increased from the former speed of 90 revolutions per minute to 250 revolutions per minute. Further changes in counter shafts have greatly increased the efficiency of the machine shop by the speeding up of individual machines. The increased efficiency of this machine shop due to the use of the Taylor-White process is shown by the following table:

Average.	Oct. 25, '98.	May 11, '99.	Jan. 15, '00.	Gain in % cut of 3d over 2d.	Gain in % cut of 3d over 1st.
Cutting speed	8' 11"	21' 9"	25' 3"	16%	183%
Depth of cut	.23"	.278"	.30"	8%	30%
Feed	.07"	.0657"	.087"	32%	24%
Pounds of metal removed per hour	31.18	81.52	137.3	68%	340%

A very interesting exhibition of the use of this steel was given Tuesday, July 30th, in which the following striking tests were made. In each of the tests made the cut was 3-16 of an inch on a side.

A high carbon steel shaft was placed in the lathe and revolved at a speed of 15 ft. per minute. After 20 minutes of cutting the Taylor-White tool was found to be only slightly nicked, while a high grade Mushet tool working under the same conditions was so dulled in 25 seconds that it would not take hold of the metal at all.

In the second test, an old roll made of hard cast iron was put into the lathe and after 20 minutes of cutting the Taylor-White tool was in perfectly good condition, while under similar conditions of operation a Mushet tool was completely worn out in 22 seconds.

The third test was of ordinary merchant steel with the lathe running at 150 ft. per minute. The Taylor-White tool steel although quickly heated to redness continued to cut, and at the end of the test lasting 4 minutes the cutting edge was still in good condition. The edge of a Mushet tool steel was burnt off short in 5 seconds. Exhibits were also given of the use of this tool steel in connection with heavy cuts at fast speeds in planer work, in forgings, and in the making of armor plate bolts.

The tool room of the machine shop of the Bethlehem Steel Co. is the best evidence of its faith in the results of the long and costly series of experiments which have been made with this steel. This room was entirely fitted up with new process tools from the planer in form to the most intricate and representing the expenditure of a large sum of money.

The Bethlehem Steel Co. will undertake in its shop any experiments to satisfy interested parties of the value of these tools. The experimental test lathe can be run at speed from 2 to 300 revolutions per minute, and will take work up to 60 inches in diameter. It is driven by an independent 40 H. P. motor giving ample power for any desired test. The Company also has on hand forgings and castings in steel and iron varying in hardness from the hardest tool steel to the softest merchant steel.

The shop right to use the Taylor-White process is being sold, the price being based upon the number of machines as well as their size and character. Many machine shop representatives have visited the shop of the Bethlehem Steel Co. to investigate the process, and already a number of foreign concerns have looked into the matter and are negotiating for its introduction abroad.

PRIZE CONTEST.

Prizes Given for the Best Answers to Questions Relating to Mining.

For the best answer to each of the following questions, the value of \$1 in any of the books in our book catalogue, or six months' subscription to MINES AND MINERALS.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue, or three months' subscription to MINES AND MINERALS.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to MINES AND MINERALS.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition Contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed to us not later than one month after publication of the question.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Ninth—In awarding prizes, other things being equal, a carefully written and arranged answer will be given the preference.

Competition Questions for September.

QUES. 612.—*Haulage, Load Upon Guide Sheaves*.—Calculate the load upon the journals of each guide sheave around a curve in a haulage road. The radius of the curve at the center line of track is 48 feet, and the sheaves are set 26 inches from track center, and 4 feet apart, center to center. The tension upon the rope is 6 tons.

QUES. 613.—*Timbering, Size of Collar*.—In the timbering of the airways of a certain mine, if we use round timber and the depth or diameter of the collars is 8 inches in an airway 8 feet wide, what should be the depth of the collars when the width of the airway is 14 feet?

QUES. 614.—*Timbering, Relation of Diameter to Length of Post*.—How should the diameter of prop timber vary with respect to the length of the prop or thickness of the seam? In timbering a certain mine, if 5-foot props are used in the rooms, and these props have a minimum diameter of 6 inches, what should be the minimum diameter for posts set upon the roads in this mine, when the roadway props have a length of 8 feet?

QUES. 615.—*Hoisting, Size of Engine*.—Calculate the size of a duplex second-motion engine geared 1 to 3, the ratio of length of stroke to diameter of cylinder being 1.25, that will hoist a maximum output of 1,000 tons per day, from a double compartment shaft 800 feet deep. The weight of the cages is 2,200 pounds each and the weight and capacity of mine cars is 1,400 pounds and 2,000 pounds, respectively. The length of a working day is 8 hours. Allow $\frac{1}{8}$ of the total moving load for friction, and estimate upon the engine as having an efficiency of 60%; the engine to cut off at $\frac{3}{4}$ stroke, the boiler pressure being 90 pounds per square inch. No balance rope is used beneath the cages.

QUES. 616.—*Tail-Rope Haulage*.—The haulage in a certain mine is to be accomplished by the tail-rope system. The distance from the tail sheave to the shaft bottom is 1,500 yards, and the shaft is 350 yards in depth, the engine being located upon the surface at the mouth of the shaft. The seam is generally flat, but there are up and down grades in the haulage road, the steepest being a 10%-grade in favor of the empties. Calculate the size of rope and the effective horsepower required for this haulage, assuming an output of 900 tons in 10 hours, the weight and capacity of the mine cars being 1,200 and 1,800 pounds respectively.

QUES. 617.—*Safety Valve*.—The distance from the fulcrum to the stem of a safety valve is 5 inches, the diameter of the valve seat $2\frac{1}{2}$ inches, the weight of the lever 15 pounds, and its center of gravity 10 inches from the fulcrum. If the ball weighs 75 pounds, how far should it be set from the fulcrum, in order that the valve will blow off at a boiler pressure of 90 pounds per square inch?

QUES. 618.—*Energy of Fly Wheel*.—The fly wheel of an engine measures 6 feet in diameter, out to out, and 8 inches on the face, the thickness of the rim being 3 inches. If this wheel is set upon

the crank shaft of a $12'' \times 16''$ engine, at what speed will the stored energy of the wheel equal the power of the engine, assuming a mean effective cylinder pressure of 50 pounds per square inch?

QUES. 619.—*Ventilation, Splitting Air Currents, Power Constant*.—The ventilation of a certain mine is accomplished by means of a fan running at a speed of 150 revolutions per minute. The maximum power of the engine is being employed, but the quantity of the air in circulation is not sufficient to meet the requirements. If it were possible, in this mine, to divide the ventilating current into two equal splits, still retaining the same power of the ventilator, would the quantity of air in circulation be doubled by this means? If you say No, please explain why.

Answers to Questions Which Appeared in the July and Previous Numbers and for Which Prizes Have Been Awarded.

QUES. 582.—(a) What rule determines the depth to which holes should be drilled in a breast of coal, in blasting? (b) What conditions determine the size or grade of powder, and amount of charge, in blasting coal? (c) State how you would proceed in mining and blasting coal, under the following conditions: The seam is a 5-foot seam of bituminous coal somewhat soft, and inclined to "seam out," in blasting; the roof is a hard sand-rock; under the coal is a 5-inch seam of good mining clay. State in detail the diameter, position, and direction of drill holes, grade of powder, and weight of charge you would employ.

ANS.—(a) The rule for drilling holes is that the depth of the hole should not exceed the line of least resistance. [The depth of the hole is also influenced indirectly by the thickness of the seam, since the line of least resistance is usually proportionate to the size of the shot or width of the heel, which practice makes proportional to the thickness of the seam.] (b) The nature of the coal as to its hardness or softness [also the character of the work—room work, pillar work, or "shooting off the solid"] determine the size or grade of powder. The width of the shot, and its adhesive nature, diameter of hole and thickness of seam, the character of the coal with respect to cleavage and cleats, all of these determine practically the amount of the charge. (c) As the shots in this case incline to seam out in blasting and the roof is a hard sandstone, the best way to work the coal would probably be as follows: Start the holes low or near the floor and incline them upward towards the roof. Drill holes of $2\frac{1}{2}$ inches in diameter. As the coal is soft the powder should be a large grained or slow powder. The weight of the charge would vary according to the thickness of the shot to be fired. The weight of the charge of powder is got by the following rule: Multiply the fourth power of the distance in feet from the center of the charge out in the direction of the line of least resistance by .4 of the diameter of the hole in inches, and divide the result by the thickness of the seam in inches. The result will be the weight of the charge in pounds. WM. CHAMBERS, Spaulding, Ill.

Second Prize.—M. Fagan, Pana, Ill.

QUES. 596.—*Retrograde and Direct Verniers*.—Explain the difference between the retrograde and direct vernier, and state how you would determine to which class a certain vernier belonged. Show a vernier of each kind and explain how it is read.

The difference between a direct and a retrograde vernier consists in the manner in which they are graduated. The terms direct and retrograde refer to the manner in which the vernier of each respective class is read. To determine to which of these two classes a

Fig. 1 Direct Reading

Fig. 2 Retrograde Reading.

vernier belongs, it is only necessary to determine the number of divisions of the main scale that correspond to the divisions on the vernier scale. Thus, if n number of divisions on the vernier scale equals $n - 1$ divisions of the main scale, the vernier is called direct; but if n number of divisions on the vernier scale equals $n + 1$ divisions of the main scale, the vernier is called retrograde.

[The divisions of the main scale always equal some unit of

length or of angular measure, foot, inch, centimeter, degree, half-degree, etc. Then, the number of parts into which this unit of the main scale is to be divided determines the number (n) of divisions of the vernier scale. Thus, a rod reading to thousandths of a foot usually has its main scale divided into feet and hundredths of a foot, and the length of its vernier scale is then made equal to 9 of these divisions, if *direct*, or 11 divisions if *retrograde*; but in each case, the vernier would have 10 divisions.]

To read a direct vernier, suppose the zero line of the vernier to coincide with some even division of the main scale, Fig. 1, [and suppose the main scale to be divided into half-degrees (30 min.), if the instrument reads to minutes, the vernier has 30 divisions, and these] 30 divisions of the vernier scale equal 29 divisions on the main scale and each vernier division equals $\frac{1}{30}$ of a scale division or 29 minutes, one minute less than a division of the main scale. Now, if the vernier is moved forward 1 minute, the first line of the vernier scale from zero in the direction in which the vernier was moved will be in coincidence with the main scale. If moved 2 minutes, the second line will coincide, and so on to the end of the vernier scale. Such a vernier is called a *direct vernier*. To obtain the total reading the main scale is read from zero to the zero of the vernier, and then the vernier scale is read forward in the same direction to its line of coincidence; thus, in this case, degrees and half-degrees (30 min.) are read from the main scale, but minutes less than 30 are read from the vernier and added to the first reading.

If the vernier is retrograde, (Fig. 2) the 30 divisions of the vernier scale will equal 31 divisions of the main scale instead of 29 as before. When the vernier is moved forward one minute, the first line of the vernier back of the zero point will be in coincidence on the main scale, and so on. Such a vernier is called a *retrograde vernier*. To obtain the total reading of this vernier, the main scale is read, as before, from zero to the zero of the vernier, and then the vernier scale is read from here backward to the line of coincidence, or in the opposite direction from the reading of the main scale.

QUES. 597.—*The Use of Wet Steam.*—What disadvantage arises in the use of wet steam, in the operation of hoisting and winding engines? Describe some efficient means at hand that will remedy this evil.

Ans.—In short-stroke high-speed engines, such as are usually employed for hoisting and winding, sharp cut-offs and small clearances are the rule nowadays. This has introduced an element of danger from water in the cylinder (the result of wet steam). A water ram is produced by the swift moving piston driving this water of condensation into the small clearance provided. This is apt to cause the wreckage of the engine by forcing out the cylinder heads and damaging the working parts.

With wet steam high efficiency can never be obtained. Outside of the liability to engine break-downs, which must be guarded against by reducing the speed of the engine, which is equivalent to a reduction of power, is the absolute reduction of work done, due to the moisture in the steam and there is the further danger of cutting the edges of valves and ports, which is not only injurious to the engine, but causes leakage and improper distribution of steam, making the expense of operation far greater than it should be with steam perfectly dry. With wet steam proper lubrication is not obtained, on account of the water destroying the action of the oil in the cylinder and valves, when cutting results. The engine is then practically in the same condition as if no oil had been used.

To overcome these evils numerous devices have been invented and applied. Relief valves, explosion diaphragms, drip-cocks, etc. are often applied direct to the cylinder, and are found effectual within the limits of their possibilities. These are, however, inadequate to remove the danger of breakage arising from the presence of water which comes into the cylinder in large quantity from undrained pipes, sudden boiler foaming, and other like causes. The most efficient means to avoid such danger is to introduce a "steam separator" between the steam supply and the cylinder, and to place it as near to the steam intake as practicable.

There are several separators in the market, of more or less merit. The most approved patterns are based on the principle that if a rotative motion is imparted to the steam in the separator, the liquid particles contained being heavier than the steam, are projected to the outside of the current against the outer shell of the apparatus, by centrifugal force, whence they flow in a thin sheet into a receptacle below. The steam, then, in a dry condition, passes out of the separator and is conducted into the steam chest of the engine without the stream of separated water.

THEODORE SIMONS, Roseland, B. C.

Second Prize.—CHAS. E. BOWRON, Birmingham, Ala.

QUES. 598.—*Essential Factors of Ventilation.*—Mention the

essential points in the ventilation of a coal mine, and describe the practical importance of each point named.

Ans.—The efficient or thorough ventilation of a mine is dependent upon three essential elements: (a) Volume of the current; (b) Manner of conducting the current through the mine; (c) Velocity of the current.

(a) *Volume of Air Required.*—The quantity of air required to be furnished per minute to the workings of a mine is usually fixed by the law of the state or country in which the mine is located. The amount specified is usually, in non-gaseous mines, 100 cubic feet per minute per man, and five times that amount per minute per mule or horse. In gaseous mines this amount is increased to 150 cubic feet per minute per man, and in some cases, as in the anthracite mines of Pennsylvania, 200 cubic feet per minute per man are required by law. This method of fixing the amount of air required is purely arbitrary, and often not adapted to the existing conditions, as the workings in a thin seam may have an abundance of air which may result in producing too high a velocity; while in a thicker seam the resulting velocity will perhaps be too low for proper ventilation.

(b) *Manner of Conducting the Current.*—The thorough ventilation of the working face in any mine is dependent to a large extent upon the manner in which the doors, stoppings, brattices, overcasts, or bridges are erected. These should not be allowed to leak.

Doors should be hung with a fall sufficient to close behind a passing car, and should be fitted tightly to a substantial frame. Where the ventilating pressure is light, a door is sometimes hung to swing both ways, to save trapping. Ordinarily, however, this cannot be done and the door must then be hung to open against the current. Canvas flaps are sometimes nailed to the bottom of a door to prevent leakage and allow of good clearance for the door. Double doors are sometimes used in cross-cuts near the shaft bottom, between the main airway and the return. The object of double doors is to prevent the momentary stoppage of the ventilating current when a car is passing through the cross-cut. The doors are set from 6 to 8 yards apart, or farther, if the length of the cross-cut will permit. Stoppings are commonly built of a double wall of slate with a few inches of space between. This space is filled completely to the roof with fine sand or clay from the surface; or fine dirt taken from the roads may be used. Stoppings upon the main air-courses of large mines are often laid up with brick instead of slate and the walls plastered with fire clay. Brattices are partitions, usually of wood or canvas (brattice-cloth), for the purpose of dividing the airway for a short distance near the face into an intake and a return. Curtains are heavy canvas hung across an airway or at the mouth of a room to partially turn the air. A curtain serves as a regulator, inasmuch as it permits a portion of the air current to pass it, while the remaining portion is forced into another passageway. Regulators are contrivances for regulating the division of air between two or more airways. Bridges (overcasts or undercasts) are built in airways for the purpose of crossing the air currents. All of these means for conducting the air current through the mine are of practical importance because efficient ventilation is dependent upon their use.

(c) *Velocity of the Current.*—This is a very important factor in the ventilation of a mine, as upon it largely depends the removal of mine gases. A body of firedamp or of marsh gas which is exuding from the coal, or has collected in some cavity of the roof, or at the face of some rise heading, will require a current having a certain velocity to dilute it and drive it from its position. In like manner the heavier gases, as carbonic acid gas, which settles in the dip workings and low places of the mine cannot be carried out if the velocity is too low. The current velocity should not be allowed to fall below 3 or 4 feet per second at the working faces. On the other hand, too high a velocity of the ventilating current is always objectionable, and, in gaseous mines, dangerous. The anthracite mine law of Pennsylvania provides that all air passages shall be of a sufficient area to allow the passing of 200 cubic feet per minute per man at a velocity not exceeding 450 feet per minute, and this velocity may be taken as a safe maximum limit in gaseous mines. It must be remembered that a safety lamp carried against a current is virtually subjected to a velocity equal to that of the current plus the velocity with which the lamp is being carried against the current. In non-gaseous mines the velocity of the main inlet may be anywhere from 10 to 20 feet per second which may not cause serious annoyance, and in many cases it exceeds this amount; but it should not fall below 3 or 4 feet per second in any airway in the mine.

JOHN COWAN, Antrim, Penna.

Second Prize.—THOMAS CHARLTON, West Leisenring, Penna.

QUES. 599.—*Extending a Mine Survey.*—In extending a previous survey in a mine, explain in what manner you would proceed, if you could find but two points of the old survey remaining in the mine, and these points were not consecutive points, or not upon

the same entry. Explain, in general, what method you consider the safest to employ in the connecting of two mine surveys underground.

Ans.—Let A and B in the figure be the two points remaining of the old survey, and whose latitudes and departures are known, referred to the meridian or base line to which all mine surveys are connected. By means of the latitude and departure method the bearing and length of the line $A-B$ may be calculated. Thus, calling the difference of latitude between A and B , x , and their difference of departure y , the bearing of the line $A-B$, a , and its length L , we have,

$$\tan a = \frac{y}{x}, \text{ and } L = \sqrt{x^2 + y^2}, \text{ or } \frac{x}{\cos a}, \text{ or } \frac{y}{\sin a}.$$

Use the old points A and B as stations of the new survey $A-1-2-3-B$. Assume any convenient approximate meridian and calculate by the latitude and departure method as shown above the bearing and length of the line $A-B$ from the notes of the new survey, referred to this approximate meridian. Where possible the survey should be extended from B around to A again, by means of stations 4, 5 and 6, as shown in the figure, and the calculation of the bearing and length of $A-B$ checked, and if an error is found, it can be corrected. Since the true bearing of the line $A-B$ is known from the first calculation from the

notes of the old survey, we correct each course of the new survey and the assumed meridian by swinging these to the right or left until the course $A-B$ corresponds to the true bearing of the line. The difference between the true bearing of $A-B$ and the bearing found by the new survey will be the correction to apply to all the courses $A-1$, $1-2$, $2-3$, $3-B$, $B-4$, $4-5$, $5-6$ and $6-A$. Now from any of these lines the mine surveys can be extended to any part of the mine.

When a mine is connected by two shafts or shaft and a slope, the safest way to connect underground surveys would be to extend from the meridian or base line a survey down each shaft or slope, and extend them until they meet at a common point. Then by the latitude and departure method errors can be found and corrected and the survey balanced. In metal mines where the only other connection between levels, besides a shaft, is by raises extending from level to level and from upper level to surface, the quickest and surest method is by connecting the surveys on each by running another survey between the levels through these raises, and following same method of calculating survey to balance it.

[In general, the safest way to connect two surveys, or to extend an old survey is to make two points at least common to the two surveys and calculate the bearing and length of the line joining these points. Use this line as a base line for connecting the two surveys. The length of this base, as calculated from the notes of each respective survey should be the same. The difference between the respective bearings of the line shows the correction of bearing which must be applied to each course in one or the other of the two surveys in order that they shall agree. The farther apart the two points can be taken, or the longer the connecting base line, the better the results obtained.]

Second Prize.—W. F. HUGHES, Plymouth, Penna.

Ques. 600.—*Engine-Plane Haulage*.—Calculate the size of rope, drum, and engine required for an output of 1,000 tons per day of 10 hours, at a slope mine, when the inclination of the slope is 30° , and its length measured upon the incline is 500 yards. Assume the capacity and weight of mine cars as 2,000 pounds and 1,200 pounds respectively. Estimate the rolling friction as $\frac{1}{10}$ of the normal pressure upon the plane. Assume a mean effective cylinder pressure of 80 pounds per square inch, and a speed of winding of 750 feet per minute, allowing 60 per cent. for the efficiency of the engine.

Ans.—Assume that the double-track system is used. Then $500 \times 3 = 1,500$ feet of winding per trip. Say it takes 4 minutes to change the ropes at the top and bottom each trip; then

a trip will be landed each $4 + 2 = 6$ minutes; and since the capacity of the mine cars is 2,000 pounds = 1 ton, we have,

$$\frac{1,000 \times 6}{10 \times 60 \times 1} = 10 \text{ cars per trip;}$$

and $10(2,000 + 1,200) = 32,000$ pounds, weight of loaded trip.

Let W = weight of ascending or loaded trip (pounds);

w = weight of rope per linear foot (pounds);

l = length of slope measured on the pitch (feet);

a = angle of inclination of slope;

T = maximum pull or load upon the rope (pounds).

The pull or load upon the rope, in this case, is the sum of the gravity pull and friction pull, and is a maximum when the last car of the trip has just left the "dish" at the foot of the slope.

We have $(W + wl) \sin a$ = gravity pull,

and $(W + wl) \frac{\cos a}{40}$ = friction pull;

hence,

$$T = (W + wl) \times \left(\sin a + \frac{\cos a}{40} \right) = \text{maximum load on rope.}$$

Size of Rope Required.—Substituting given values in the above equation and assuming an approximate value for w , of say 3 pounds, we obtain

$$T = (32,000 + 3 \times 1,500) \left(.5 + \frac{.866}{40} \right) = 19,040 \text{ lb., say } 19,000 \text{ lb.}$$

Multiplying this by 2 to provide against shock, and using a factor of safety of 6, we find the breaking load of the rope should be

$$\frac{19,000 \times 2 \times 6}{2,000} = 114 \text{ tons.}$$

Referring to the table given on page 379 of the March issue of MINES AND MINERALS, we find that a $1\frac{1}{2}$ -inch plough steel rope, weighing 3.65 pounds per lineal foot, has a breaking strain of 110 tons, and will therefore be suitable for this load. Correcting for the excess of weight over that of the assumed rope, we find for the maximum pull on the rope

$$T = (32,000 + 3.65 \times 1,500) \left(.5 + \frac{.866}{40} \right) = 19,548.8 \text{ lb.,}$$

say 19,550 lb. Hence, using this rope, we have for a factor of safety $\frac{110 \times 2,000}{19,550 \times 2} = 5.62$, which is ample.

[There is some difference between the weights and breaking strains of 7-wire haulage ropes (see Table, page 522, MINES AND MINERALS, June, 1900) and those of 19-wire hoisting ropes (Table, page 379, MINES AND MINERALS, March, 1900). The former should have been referred to in place of the latter, but the difference is small.]

Load Upon Engine.—Using the same notation as before and letting

W_1 = weight of descending empty trip (pounds),

L = load upon the engine, or difference between the ascending and descending pulls (pounds),

we have,

$$L = (W - W_1 + wl) \sin a + (W + W_1 + wl) \frac{\cos a}{40}.$$

Substituting the given values, we have

$$L = (32,000 - 12,000 \times 3.65 \times 1,500) \left(.5 + \frac{(32,000 + 12,000 + 3.65 \times 1,500) .866}{40} \right) = 13,808.6 \text{ lb.}$$

Size of Engine Required.—The horsepower of each cylinder will be

$$\text{H. P.} = \frac{13,808.6 \times 750 \div 33,000}{33.8} = 314 \text{ effective horsepower.}$$

With an engine efficiency of 60 per cent., the total horsepower required will be $314 \div .60 = 523.3$, say, 523 horsepower.

Assuming a second-motion duplex engine, running at 240 strokes per minute, and the ratio of the stroke to the diameter of the cylinder, $\frac{1}{4}$,

$$d = \sqrt[3]{\frac{u}{.7854 \times p \times r \times n}}$$

where d = diameter of cylinder (inches),

u = work per minute (inch-pounds),

r = ratio of stroke to diameter of cylinder,

p = mean effective cylinder pressure (pounds per square inch), and

n = number of strokes per minute.

Substituting the given values, we have,

$$d = \sqrt[3]{\frac{523 \times 33,000 \times 12}{.7854 \times 80 \times \frac{1}{4} \times 240}} = 21.76, \text{ say, } 22 \text{ inches,}$$

and the length of stroke = $21.76 \times \frac{1}{4} = 5.44$ inches.

Making the diameter of the drum 80 times that of the rope,

we have for the diameter of the drum $1\frac{1}{2} \times 80 = 120$ inches = 10 feet.

Let r_1 = the ratio of the diameter of the gear wheel to the diameter of the pinion,

v = the speed of winding (feet per minute),

D = the diameter of the drum (inches), and

n = the number of strokes per minute.

Then we have,

$$r_1 = \frac{\pi D n}{2 \times 12 \times v}$$

Substituting the given values, we have

$$r_1 = \frac{3.1416 \times 120 \times 240}{2 \times 12 \times 750} = 5, \text{ nearly.}$$

Therefore, the gearing should be in the ratio of 5 to 1.

EVAN C. DAVIES, Duryea, Penna.

Second Prize.—J. EDWARD MILLS, Belle Vernon, Penna.

QUES. 601.—*Second-Motion Engines*.—What advantages are to be gained in the use of second-motion engines? Describe the general conditions under which they should be employed in hoisting and haulage.

Ans.—The advantages of second-motion engines are: (1) Slow starting and landing speeds. (2) Speed of winding more easily controlled by the engineer. (3) Smaller size engine required for the same load. (4) High piston speed with economy in use of steam.

In general we would use this kind of engine for short and moderate length hauls, hauls somewhat longer, but with difficult landings, and in places where boiler pressure was rather low.

First Prize.—CHAS. E. BOWRON, Birmingham, Ala.

QUES. 602.—*Percentage of Gas in a Ventilating Current*.—The ventilating current in a certain district of a mine is charged with gas to the amount of 3 per cent., as shown by the Shaw gas-testing machine. The ventilating pressure in this mine gives a water gauge of 2½ inches. A fall upon the main intake has so reduced the volume of the air current that the water gauge reads only 1 inch. Determine the percentage of gas in this current.

[Many have failed in their replies to this question, which is in no sense a catch question, but one requiring a little thought. In an analysis of this question, which should always be made first, it would be well to ask the following:

1. Where is the quantity q measured?
2. Does this contain gas?
3. Where is the gas test taken?
4. What volume of gas relative to the circulation (q) does 3 per cent. represent? Is the gas 3 per cent. of q ?—EDITOR.]

QUES. 603.—*Ventilation of Dip and Rise Workings*.—An inclined seam is worked both to the rise and dip from the bottom of the shaft. The inclination of the seam is 35°. The length of the main incline to the rise is 400 yards, while the dip has a length of 300 yards. The average temperature of the intake airway to the rise is 45° and to the dip 50°; while the temperatures of the return currents, after traversing the gangways of the rise and dip workings are 60° F. and 70° F., respectively. The ventilation in this mine is produced by a fan which is circulating a current of 80,000 cubic feet per minute; 50,000 cubic feet going to the rise workings and 30,000 to the dip workings. The water gauge at the foot of the shaft is 1.5 inches. Owing to an accident the speed of the fan has been reduced and the water gauge has fallen to .5 inch. Determine the quantity of air that will be in circulation under these conditions in both the rise and dip workings.

[No correct answers to this question have been received.—EDITOR.]

The Williams Pulverizer.

The accompanying cut shows a sectional view of the Williams patent pulverizer and crusher made by the Williams' Patent Crusher & Pulverizer, Co., 2701-2707 North Broadway, St. Louis, Mo. This crusher although comparatively new has been quite widely adopted and the reports of the work being done by it are very favorable. The cut here shows the mechanism of a No. 3 crusher designed to take run of mine coal and reduce it to any size down to coarse meal. The crusher works on the hinged hammer principle, the hammers being pieces of steel 4" in width and 1" in thickness, weighing about 16 lb. each and swung upon steel bolts 1½ inches in diameter. The center shaft 4" in diameter is mounted on self-oiling dust proof journal boxes and upon the

WILLIAMS HAMMER PULVERIZER.

shaft are disc plates made of cast steel 1" thick which carry the hammers. The shaft revolves at 800 to 1,500 revolutions per minute, the coal being struck by the point of the hammer only and each hammer striking not more than ¼ inch surface of the coal at one time. At a speed of 100 revolutions per minute 52,000 blows per minute are struck, thus insuring very rapid breaking and pulverizing. To regulate the size of the crushed material the machines can be easily adjusted.

The peculiarities of these machines are that they reduce and break by a combination of abrasion and percussion. Owing to the hinged character of the hammers the accidental introduction of a horseshoe or a railroad spike in a hopper does not injure the crusher. The hammers are easily replaceable by any blacksmith and the cage bars are also equally easy of renewal. The hopper also has a removable breaker plate which can be reversed or renewed when worn out. The crushers thoroughly crush and mix the coal and reduce it to a uniform fineness. The percussive blow thoroughly loosens the tissues and fiber of the coal so that when placed in the coke ovens it cinders together and the heat penetrates uniformly all particles of coal, producing hard fine coke uniform in structure.

About 400 of these pulverizers are at present in use in the United States and Great Britain and the reports of their working are very satisfactory indeed. Complete details and particulars can be secured from the Williams Co.

MINING WRINKLES.

For original contributions upon mining or metallurgical topics descriptive of new and handy devices and appliances we will pay at the rate of five dollars (\$5) per column, payment to be in technical or scientific books to be chosen by the contributor.

Water Car.

By Daniel Weston, Black Diamond, King County, Washington.

No doubt many of the readers of MINES AND MINERALS have had trouble with water cars when the water has risen above the guide rails, or some other appliance used for keeping the car from floating when it strikes the water.

I experienced this trouble myself some years ago. To overcome this difficulty I conceived the idea of attaching a piece of sheet iron to front of car. The sheet to be the same width as car, and length from three to four feet according to pitch of slope. The sheet does not require to be as long on, say 45° pitch as it would on 35° for the sheet would be more submerged on the former than latter pitch and the water would exert more pressure on same. The sheet can be bolted to bottom of car with stays running from front of sheet to top of car. This idea has been put into effect and is still used here and it has given entire satisfaction. The plate can be put on so that it can be taken off when there is no use for it.

A New Device for Reheating Compressed Air for Use in Pumps.

Too much attention has been given of late to the economical production of compressed air to the detriment of the economical use of compressed air in motors. As applied at present to the ordinary direct-acting steam pump there is utilized only a fraction of its intrinsic energy, and many are the complaints directed against the economy of compressed air, on account of the very small returns which are made by these pumping devices.

Of course the readiness with which an ordinary direct-acting steam pump can be set up in a mine, and air turned into it, is the great reason for the numbers which are in use today. In other words, the problem is one of utility rather than economy. An ordinary direct-acting pump does not use air expansively, therefore but little can be expected from it, about 20 per cent. of the useful effort of the air being all that is converted into water pumped.

In many places pumps of this character cause considerable annoyance from freezing, and for this reason compound direct-acting pumps cannot be used with cold air. One can readily see that if the temperature of the exhaust of an ordinary direct-acting steam pump is from 20 to 30 degrees below zero, which frequently causes stoppage from freezing, that to exhaust this low temperature of air in a compound cylinder and further reduce its temperature to perhaps 100 would be an impossibility, because it could not work longer than the time which it took to reduce the temperature of its cylinder to the freezing point.

A compound direct-acting pump, which is heated sufficiently to prevent its freezing, will pump twice as much water for the same amount of air as a single-acting pump. If a single-acting pump will not freeze in working under ordinary conditions, introducing the air into the cylinder, we will say at 60 degrees temperature, the compound pump will not freeze if the air entering the compound cylinder be brought up to this same temperature.

If the ventilation in a mine is such that a reheater can be established underground, of course there is no difficulty whatever in running compound pumps, and very economically at that. There are some mines that do not object to carrying a steam pipe into the lower levels for the purpose of furnishing heat for the low pressure cylinder, but such opportunities are infrequent, inasmuch as the temperature of the mine is raised to an undesirable point, and in carrying steam a long distance it becomes an expensive operation.

A problem which occurred to the writer was to attempt to run plain compound pumps without any extraneous source of heat by utilizing simply the heat stored in the water being pumped at ordinary temperatures. The result was an installation of a Worthington pump having a capacity of 200 gallons per minute at a lift of 600 feet in the Gwin mine, Calaveras County, California.

The manner in which the installation was made was as follows: A 300-horsepower Wainwright copper corrugated heater was placed in the suction pipe of the pump, the water being pumped passing through the corrugated copper tubes at a temperature of from 60 to 70 degrees. The air after being exhausted from the high-pressure cylinder at a pressure of about 35 pounds, passes into the shell of this reheater and around the outside of the copper tubes. The extremely low temperature of the exhaust from the high-pressure cylinder is thus neutralized

by coming in contact with the water in the copper tubes, while the temperature of the air is raised to practically that of the water. It then passes to the compound cylinder, does its work and is exhausted without freezing.

Before installing this compound pump on the 600-foot level of this mine a Worthington sinking pump had been used to pump out the water. The compressor furnishing the air to this pump made 55 revolutions to actuate it and to supply power for a hoist and to overcome pipe leakage, the latter two items taking about 20 revolutions of the compressor, leaving 35 to be used for the pump. When the compound pump was put in place the revolutions of the compressor dropped down to 35, which showed a gain of 50 per cent. in favor of the compound proposition with its reheating.

The work being done at this mine was to pump out an old shaft 1,500 feet deep, which had remained idle for about twenty-five years. The water was therefore foul and inky in color and full of decomposed slates. This frequently coated the inside of the copper tubes and materially lessened their conductivity for the heat contained in the water, the result was that the pump froze up. After cleaning the tubes, however, the pump operated as freely as before, showing conclusively the advantage of the system.

A still further gain would have been accomplished had the pumps been specially constructed for this character of work and the high- and low-pressure cylinders been water-jacketed, permitting either the suction or the discharge water passing around the jackets and thus keeping them at an even temperature.

This apparatus can be installed in the discharge pipe or in the tank adjacent to the pump where the water accumulates in the mine and can overflow it freely. Moreover, this is the proper manner of applying heat to air used in a compound pump. Many pumps have the air heated before it goes into the initial cylinder, which is economical as far as the initial cylinder is concerned, but by actual observations the writer has found that the clearances between the high- and low-pressure cylinder are such that the exhaust from the high-pressure cylinder loses a considerable portion of its pressure before the stroke commences, and the drop in pressure causes such a drop in temperature of the air entrained between the two cylinders that the virtue of the reheating affects but slightly the compound cylinder where it is most needed. To be really an economical proposition the air should not only be heated before it goes into the high-pressure cylinder, but in the receiver between the two cylinders and also in jackets around the two cylinders. There is no doubt that by doing this reheating properly in compound pumps where steam or highly reheated air is used, that the efficiency of this pump can still further be raised 25 per cent.

If compressed air engineers desire to hold their own against the installments of electrical pumps they must employ more economical processes for pumping water, and pump builders can assist materially in constructing pumps properly for such work, and the above device will be found extremely economical and useful where heat cannot be safely introduced underground. —E. A. Rix, in *Compressed Air* for July.

Tungsten.

A paper on this rare metal was read before a meeting of the Mining Society, of Nova Scotia by Mr. A. C. Ross. He said it was usually found associated with tin, and in an ore known as wolfram or wolframite. The metal is especially valuable as an alloy for steel, on account of its hardening, toughening and self-tempering qualities. It only requires 9 per cent. of tungsten to be alloyed with steel to give a self-tempered tool steel of great durability. "Mushet" steel, manufactured at Sheffield, contains this percentage, and sells for seven times as much as the highest priced ordinary tool steel. Tungsten steel has great magnetic properties, some specimens showing as high a remanent magnetic moment as 62 units, as against 37 units for "diamond steel," 5 units for "Martin steel," and only 3 for "Bessemer steel." The production of the metal today in the world does not exceed 1,000 tons. The demand greatly exceeds the supply even with the existing high prices. Ore has been discovered during the past year in Nova Scotia, but to what extent is as yet unascertained, which analyzes as follows:

Tungsten trioxide	66.32
Silica	6.25
Manganese	12.02
Iron	.12

In the case of the real wolfram the percentage of iron is much higher, and this tungsten must rather be called a hibrenite, which is supposed to be rarer than wolfram. It is a difficult metal to mine, occurring in bunches in the vein, which itself twists about in an extraordinary manner. Besides the present discovery, deposits are worked in Germany, Bohemia and Texas, while it has recently been found in Nevada. It also occurs in the Cornish tin mines.

LAKE SUPERIOR COPPER MINES.

Why the Copper Output Does Not Respond as Readily as the Iron to an Increase or Decrease in Price.

Written for MINES AND MINERALS, by H. J. Stevens.

The difference between the iron and copper mining industries is a radical one, much as the two lines of mining resemble each other at first sight. The iron trade has been aptly called the barometer of American business interests, and like the real barometer with its column of mercury, the fluctuations are numerous, and at times sudden and severe. The average iron mine can be reopened on short notice after long idleness, but the reopening of a copper mine is a matter of years. The iron miner must adjust his efforts to the requirements of the market for the near future, while the producer of copper is necessarily working with a view to the general average of conditions for a decade to come, being unable to adjust his efforts as a whole to the minor fluctuations of the copper market. The big mines can, of course, adjust production to immediate demand to some extent, but the fluctuations in output of even the largest mines are comparatively slight. The stimulus of very high prices enjoyed by the Lake Superior copper mines for the past two years has resulted in increasing the annual production of the red metal less than 10 per cent. per annum. John Stanton, of New York, the veteran authority on the American copper trade, estimates the increase of product of copper for the entire United States at no more than 10 per cent. for the year 1900, the increase for the first half of the year being but 9 per cent. This increase is barely sufficient to provide for actual requirements, and the increased production of foreign lands is scarcely as great as the average in this country.

Despite the many flourishes of trumpets and the tens of thousands of dollars expended in the columns of the press, advertising the numerous Calumet & Hecla in embryo, which were to make their shareholders wealthy on small investments, the production of all the new mines, together with the increased output of all the old mines, did not exceed 10 per cent. last year, will not exceed the same amount this year, and probably will show no greater gain in 1901. The immediate future of the copper market seems assured. With a strong and steady demand for all the copper that can be mined, the price of the metal, high though it may be, is supported by the logic of demand and supply. What may be the future of the copper market in five or ten years is a matter of conjecture. The high price is stimulating production, and while, from the peculiar conditions surrounding copper mining, it is impossible to open new mines rapidly, the nature of the business is such that a strong stimulus once applied is more lasting in its effects than in industries where supply can more readily respond to demand. There are many good copper mines being opened throughout the Union, and many more new mines in other countries.

In a few years the effect of renewed effort in copper mining over the entire globe must be plainly felt in largely increased production. This much is certain, and what the effect of doubled production will be within six or seven years must depend almost wholly upon the progress of electrical development. Should the utilization of electricity proceed at its present rapid rate of increase both in America and abroad, the world's supply of copper in 1907, which will probably be nearly double the production of 1900, will no more than meet requirements. Should, however, there be a marked falling off in electrical construction, either in the United States or Europe, or in both, there will be hard times in store for many of the mines, and 8-cent copper is probable for a time. The best mines of Michigan, Montana, and Arizona are making copper at 6 to 9 cents per pound, and the cost of production can be materially cut if the necessity arrives. The mines are now earning larger profits than ever before in their history, and are paying the highest scale of wages, while expenditure is not being stinted in any direction. This policy of lavish expenditure in prosperous times is censured by many short-sighted and greedy shareholders, who grumble because all of the vast profits are not paid out in dividends as rapidly as earned, but the well managed mines are putting themselves in splendid position for withstanding the slings and arrows of outrageous fortune when a time of trouble comes. Enormous surplus funds are being accumulated, new mills are being constructed and filled with the best and costliest machinery, new docks are being dredged, wharves and warehouses built upon their banks, railroads are being constructed, shafts enlarged, mammoth hoisting plants and air compressors installed, houses erected for employes, and money is flowing like water into scores of channels. Perhaps some of this cash is wasted, but the greater part is being wisely expended, where it will remain in safety and return good interest. All these expenditures mean greater efficiency in mining and milling—a large scale of operations, greater

production per man, smaller losses in the tailings, with mining, transportation, and milling charges reduced to the minimum. When the time comes, as come it must, sooner or later, when the metal again sells at 9 cents or lower, the good mines now spending money so freely will be in a position to rest on their arms and earn excellent profits at almost any selling price for copper. The expensive construction work now under way can be reduced to a minimum and, in many cases, done away with entirely. A cent or two, or even three, can be cut from the cost of making copper, without seriously reducing wages. In addition to the saving thus made possible, the cash surplus funds will act as a balance wheel and will enable regular payment of dividends regardless of sudden fluctuations in the metal market.

The theory and practice of mining are nowhere in a more advanced state than in the Lake Superior copper district. Nowhere upon the globe are the mines so deep or so well equipped with machinery of the largest size, though the Transvaal mines of South Africa are a close second in these particulars. The largest mines of the Lake copper district have taken another great step in advance, by their methods of finance, and to a large extent have eliminated the element of chance from the fiscal conduct of their properties. The copper-bearing lodes of amygdaloid and conglomerate found in this district are of altogether exceptional permanence and uniformity. Unlike the gold, silver, and copper mines of other districts, operated on fissure and contact veins, the cupriferous lodes of the Keweenaw Peninsula are apparently bottomless, though as a matter of fact the copper-bearing formation extends under the bed of Lake Superior, the reverse fold of the synclinal outcropping on Isle Royale, 40 miles to the northward of the shafts on the mainland. This eliminates very largely the element of hazard as to the continuance of the mineral reserves which are the future life of any mine, and the conservative managements of several of the best properties have pursued a fixed policy of betterments in prosperous times, and steadily increasing surplus funds, which have finally placed their shares with the best managed railroads or manufacturing concerns. Mining is usually regarded as a hazardous occupation for workmen, and an extra hazardous investment for capital, but thanks to a happy combination of practically inexhaustible ore bodies and far-sighted financing, the best of the Lake Superior copper mines have advanced into a new class of preferred investments.

OBITUARY.

JASPER R. RAND was born September 17, 1837, in Westfield, Mass., of a family dating its American ancestry from 1635, and including two colonial governors; and which was well represented in the Revolutionary War. He obtained his education in the public schools and academy of his native town and in Fairfax, Vermont. His earliest business connection was with his father, who was a manufacturer of whips when Westfield was the headquarters of that industry. In 1865 his father retired from business, and Mr. Rand and his younger brother, Mr. Addison C. Rand, succeeded him.

In 1870 he removed to New York, and was for a time associated with another brother, Mr. Albert T. Rand, president of the Lafin & Rand Powder Company. In 1872 Mr. Addison C. Rand began the manufacture of the Rand rock drills and other mining machinery, and the two brothers subsequently organized the Rand Drill Company, with Mr. A. C. Rand as president and Mr. J. R. Rand as treasurer, which arrangement continued until the death of Mr. A. C. Rand in March last, which left the chief office vacant, when Mr. J. R. Rand was elected to the position.

When the Messrs. Rand became interested in rock drills, they were in the pioneer stage, with—at most—a small and uncertain future before them, but they have come to be an essential part of every mining outfit. Rock drills were among the first American machinery products to find recognition among foreign engineers, and they are today at work in nearly every country on the globe where the mining industry has passed beyond the most primitive stage.

In 1873, Mr. Rand removed his residence to Montclair, N. J., where he has ever been prominent in local affairs. For three years he served on the Town Council; was for two years a chosen freeholder of Essex County; a charter member and first president of the Montclair Club, serving also another term; for fifteen years he was a trustee of the Congregational Church. He was one of the organizers of the Bank of Montclair, of which he was continuously the president. He was a member of the New England Society, the Hardware Club, and Engineers' Club of New York City; and for forty years a member of the Mt. Moriah Masonic Lodge of Westfield, Mass.

He was practically acquainted with every field of business life from that of traveling salesman up. He had a remarkable fund of wit and of pointed, but stinging, repartee, which made him the most delightful of companions—qualities which naturally

brought him friends without limit. These and other qualities also made him a presiding officer under whose gavel it was a delight to sit. He was interested in all public enterprises and contributed generously to their support.

Mr. Rand died Wednesday, July 18, and was buried at Westfield, Mass., July 20. He leaves a widow, a daughter, and a son, the latter now representing the Rand Drill Company in Paris.

COLONEL J. D. KASE, manager of the North Carolina Steel and Iron Company, died at Greensboro, N. C., on Monday evening, July 9. Colonel Kase has been a resident of Greensboro since 1891, when he went there to assume the position of manager of the above named company. He was a native of Pennsylvania, and for many years was connected with the iron industry at Danville, in that State. He was a graduate of Washington College, Pa., and 66 years of age. Some years ago, he accompanied the late Congressman Kelly, of Pennsylvania, to Alabama, and looked into the matter of developing what was then the dormant iron industry of that State. This trip, and the subsequent work of Messrs. Kelly and Kase, was a great factor in the development of the iron industry of Alabama. Colonel Kase was a man of sterling honesty and great ability, and his death is a decided loss to his adopted State.

JOHN R. DAVIS, of Scranton, Pa., died at his home in that city Thursday, August 9, after an illness of six months' duration. Mr. Davis was 78 years of age, and had been a resident of Scranton for the past 40 years. He was born in Norristown, Pa., March 27, 1822, where he spent most of his younger days. At the age of 18 he took charge of a country school, but soon entered business in Philadelphia, and later in Pottsville, where he was clerk for a coal operator. He later had charge of the coal department of the Ashland Iron Works at Wrightsville, York County, Pa., and still later engaged in the retail coal trade in Baltimore, Md. In 1851 he took charge of the Black Diamond Colliery, Wilkes-Barre, Pa., and in 1855 came to Scranton, where he built and owned the Stafford Meadow Brook Colliery. Since that time he has been closely identified with the mining interests of the Lackawanna Valley.

FRANKLIN PLATT, the well known scholar and scientist, died recently at Cape May, where he was spending the summer. Mr. Platt was a Philadelphian by birth, and since his early boyhood has been devoted to the study of geology and kindred subjects. Early in life he served on the Geological Survey of the United States Government, and in later life has acted as geologist for many corporations and business men, his reports and books based on these resources being well known. He was at one time president of the Rochester and Pittsburgh Railroad. He was a member of numerous Philadelphia clubs, of the American Institute of Mining Engineers, the Philadelphia Geological Society, the Historical Society, and numerous other scientific bodies.

Mechanical Gold Washer.

The W. J. Clark Co., of Salem, Ohio, has placed on the market a mechanical gold washer for cleaning up battery and pan residues which have heretofore been hand panned. It is also designed for placer mining where the ground is rich and water scarce.

The washer measures, when set up ready for use, 18 inches wide, 4½ feet long, and 3½ feet high. The framework is made of ½" × 1½" wrought iron, and the pans and screens are made of No. 16 galvanized sheet steel. The hopper has a "grizzly" 10 inches wide by 17 inches long with perforations ½" × 1½". The perforations in the upper screen are ½" × ¾", and in the tail screen ¾" × 1". The hopper has an adjustable gate on the side next to the pump which discharges the material onto the screen in the rocking pan. The pump has a 4½ inch bucket, and a spout 7½ inches wide which spreads the water over the material as it is discharged from the hopper. The ends of the pump levers strike buffers on the hopper (which is on pivots) and give it a rocking motion, while the rocking pan, carried on swings, is given a back and forth movement by means of toggle links connected to the pump levers, so that the pan has double the number of motions of the pump.

In the bottom of the rocking pan is a riffle tray with 11 cast iron grooved riffles for catching the gold. Beneath the riffle tray, burlap is placed to catch fine gold. The tail screen gets motion from the rocking pan, and has a pocket to catch the nugget gold which is not retained by the riffles, and the

tail screen delivers into a mercury trough which ordinarily catches the floating gold, but when there is much fine and floating gold, amalgam plates may be readily inserted.

The bottom pan contains an inside tray with plain riffles, over which all the water flows, and the tray is removable for cleaning out. The bottom pan also has a pipe plug at the lowest end for draining all the water out when required. It takes about 12 gallons of water to fill the lower pan. The pump takes its supply from this pan, and the machine is so arranged that the water from the washing process flows into the bottom pan, and is thus used again and again continuously, requiring very little addition of water to keep the machine in operation. The capacity of the washer is said to be 200 to 300 cu. ft. of material per day when operated by two men, while one man can with it clean ten to twenty times as much as he can with a hand pan. The other advantages claimed for it are that it will catch fine gold that could not be saved by hand panning; it can be operated satisfactorily in many places where hand panning is not profitable; it can be taken apart easily and packed in the lower pan (without boxing), and measures when thus packed 15 inches high × 18 inches wide × 4 feet long—weight, 250 pounds; it can be set up readily by bolting together, suitable wrenches and a duplicate set of the parts most liable to wear, being furnished with each machine.

TRADE NOTICES.

The Campbell Coal & Coke Co., A. M. Schenck, manager, Woody, Tenn., will soon be in the market for a complete mine equipment.

The Truax Mfg. Co., of Denver, Col. reports recent orders for its regular pattern and side dump automatic ore cars, from points in Virginia and Vermont.

The Williams Patent Crusher & Pulverizer Co., 2701-2707 North Broadway, St. Louis, Mo., reports daily orders for its well known crushers, from coke makers and those wishing the coal crushed into fine slack for flushing purposes and from manufacturers of cement.

The Burt Mfg. Co., of Akron, Ohio, has made some important shipments of Cross oil filters on export orders in the past month. These orders come from Denmark, Sweden, Spain, France, England and Mexico. Notwithstanding the unsettled condition of Europe, their export business is steadily increasing.

The M. C. Bullock Mfg. Company has recently sold a diamond drill to the government of Chili, and another to the government of Nova Scotia. Within 30 days diamond drills have been sent to Spain, Japan, Turkey, Antofagasta, and various parts of the United States. The following have also been shipped, a compressor and rock drill plant to the Sea of Azof; two mine ventilators to West Virginia; hoisting plants to the Black Hills, Mesabe Range, and Illinois Coal Fields; a Willans engine to St. Petersburg, another to the Massachusetts State Farm, and an 800 I. H. P. Corlies engine is now being erected for the American Cereal Company.

The Borden & Selleck Co., 48 to 50 Lake St., Chicago, manufacturers of conveying machinery of all kinds, and general agents for the Howe scales, reports being behind on orders for scales and warehouse trucks. The company looks for continued good business through this year, except in sections where crops are poor. Among recent orders completed or under construction, taken by the company are the following for conveying machines: Soo Line, freight handling conveyors run by a Howe 30 h. p. gasoline engine for transferring freight at Gladstone, Mich.; Rutland Transit Co., new warehouse equipped with five freight carriers on incline for handling freight from dock to freight house and to boats; coal handling machinery and coal screens, including rope transmissions and gasoline engines for the following: Koenig Coal Co., Detroit, Mich.; O. S. Richardson & Co., Chicago; Uhrig Fuel Co., Milwaukee; North Ave. Fuel Co., Milwaukee; C. Reiss Coal Co., Ashland, Wis.; and H. M. Benjamin Coal Co., Milwaukee, Wis.; coal and ash handling machinery for the Evansville Cotton Mfg. Co., Evansville, Ind.

As suggestive of the fact that just as hot and fluid iron can be produced in a cupola operated by a fan blower, as is necessary even for stove foundry conditions, the following statement from James McKinney & Son, of Albany, N. Y., is of interest:—"We cannot use a dull iron, therefore the above melting, (9½ pounds of iron per pound of coal) means that the iron comes out of the cupola just as hot as would be used in the ordinary stove foundry. We can melt on an average in our cupola, 5 tons in not to exceed 1 hour. In many cases we do much better than this, depending upon how much we let the blast in. In a heat of 10 tons we can melt the iron in from 1½ to 1¾ hours."

PERU'S MINING INDUSTRIES.

Facts In Regard to the Various Ores and Minerals and the Extent to Which They Have Been Exploited.

Written for MINES AND MINERALS, by H. L. Geissel.

The exploitation of mines constitutes at present, perhaps more than ever before, a rich resource for the future of the Peruvian Republic.

Peru is, indeed, one of the countries of the world whose soil contains the greatest variety of minerals. In the north we find petroleum and the sulphur of Piura; the coal deposits of Hualgayoc, and the important beds of argentiferous lead of Ancash. In the center there are the great mining districts of Cerro de Pasco, and of the Province of Huarochiri with the famous copper mines, argentiferous lead, coal, rock salt, etc.; the phosphates of Ica and the ancient quicksilver mine of Santa Barbara. In the south, we find the borax of Arequipa, the gold-bearing veins of Huayllura, Sandia, Carabayá, and the placers of Inambari.

The total number of mines under exploitation is estimated at about 2,500 and the workmen employed at 70,000. The value of the minerals exported has increased by 56 per cent. within two years, and amounted, in 1898, to 9,481,213 soles, or, taking the silver sol at the average rate of exchange for that year, viz., 42 cents, at \$3,982,109.

The following remarks give a clearer idea of the mineral richness of Peru:

Aluminum.—Sulphates of aluminum occur in pretty large quantities in the northern provinces, but the deposits are not being worked; smaller deposits of phosphate of aluminum and copper (turquoise) have also been found in the neighborhood of Huari, in the province of Azacucho.

Antimony.—This mineral occurs in almost all forms all over Peru. The abundance is so striking that the population of the Andes Cordilleras attribute the mountain sickness, known under the name of "soroche," to the antimony evaporation. The exportation of this mineralizing substance and its combinations is at present effected via the port of Mollendo. In 1898, the exportation reached the amount of 27,186 tons, of which 23,255 tons went to the United States and the rest to Great Britain.

Silver.—Pure silver exists in small quantities; it chiefly occurs in connection with copper, lead, and other minerals. In these forms it is found in the provinces of Ancash, Junin, and Lima, where one encounters the rich mines of Huaraz, Cerro de Pasco, and Huarochiri. Contrary to all expectation, the decrease in the value of this metal and the suspension of coining silver money in Peru, have not decreased its exploitation, and its exports show rather a notable tendency of increase. Thus, in 1893, the exportation of silver was as follows:

	Kilograms.
Silver bars, etc.	89,959
Silver minerals	13,772,480
Silver and lead minerals	837,178
Silver and copper minerals	964,748
Silver lead and gold minerals	22,356
Sulphurous silver	188,135

Arsenic.—Native arsenic appears only in small quantities; in the central provinces arsenic occurs in the form of sulphur, chiefly accompanied by metallic sulphurs, such as mispickel, enargite, and some varieties of gray copper ore. It is, however, very little exploited.

Bismuth.—This metal occurs associated with iron, antimony, silver, and other ores; the most extensive combination is the chiviatite which exists in large quantities in the provinces of Cerro de Pasco and Huarochiri. In 1898, 400 kilograms of bismuth were exported through the port of Mollendo.

Borax.—for several years the attention of capitalists and financiers has been especially attracted by the bborates of soda, calcium borates, and the borax occurring in the provinces of Arequipa and Tacna.

During the last few months new deposits of borax have been discovered at Azangaro (Province of Puno), at Camana (Province of Arequipa), and at Parinacochas (Province of Azacucho), in the southern part of Peru. All the deposits occur at great distances from the coast, and the products have to be carried on mule or llama back to the railway which connects Sicuani, Puno, Arequipa, and the port of Mollendo.

The principal deposit in exploitation is that of Salinas, situated some 25 miles from Arequipa and 2,000 feet above the level of the ocean. It is the property of a German syndicate. In 1897 these deposits yielded nearly 25,000 metric tons of borax.

An English company, with a capital of \$7,000,000, "The Borax Consolidated, Limited," was recently formed at London for the purpose of engaging in the exploitation of borax deposits in Chile and Peru.

The borax is chiefly exported to Great Britain and Germany, and, to a smaller extent, to France and Belgium.

Bituminous Coal.—The different varieties of bituminous coal which occur in almost all parts of Peru, form an unappreciable reserve of richness and revenue for the future of Peru.

The absence of wagon roads and railways is today the only obstacle which has so far prevented the exploitation of mines which would be more than sufficient to feed all the markets of the western coast of America.

The two principal deposits so far known are situated in the north of Peru, in the provinces of Cajamarca and Libertad. The first one, which lies in the neighborhood of Cajamarca, embraces two coal beds extending in a length of from 20 to 25 miles; one between Hualgayoc and Chota, and the other one in the neighborhood of the Marañon River. The distance which separates these two coal beds from a navigable route is 320 miles towards the Marañon (Amazonas), and 160 miles towards the Pacific Ocean.

The second deposit is situated in the province of Libertad, 32 miles south of Huamachuco. Some of its beds, extending in a length of from 20 to 25 miles, have a depth of from 20 to 34 feet. Mining engineers say that this coal is almost absolutely pure, and compares very favorably in quality with the best Pennsylvania coal.

Important coal deposits exist also in the province of Junin (Cerro de Pasco, Yauli, Huancayo). In certain localities it is converted into coke. This coal contains a high percentage of gas which could easily be made profitable if proper steps were taken, but the gas is now entirely wasted.

Copper.—The new applications of copper in different industries, particularly in the manufacture of telegraph wires, and the increase in the price of this metal on the English and American markets have had their counterpart in Peru.

The growing demand has induced many capitalists to restart the exploitation of mines which had been entirely abandoned for a long time, and to form new companies to engage in copper mining and in the exportation of this metal on a scale hitherto unknown.

In 1898 the exports of copper from Peru amounted to 1,421,119 kilograms, made up as follows:

	Kilograms.
Great Britain	1,374,959
Chile	19,246
Germany	15,273
France	11,641

It will be seen from these figures that for the moment Great Britain is almost the absolute master of the Peruvian copper market.

There exist in Peru a considerable number of copper-bearing veins whose exploitation had to be abandoned on account of the decrease in the copper prices and the increase in the working expenses, for most of the argentiferous ores contain a certain proportion of copper. One can, however, unite the copper mines now forming the object of serious exploitation into three groups, viz.:

(a) The mines in the neighborhood of Ica, where work was abandoned in 1892, containing very varied kinds of materials. During many years they yielded ores of an average richness of 30 per cent., and could today offer a good prospect to foreign capitalists if the lack of water and fuel were not two drawbacks, which, however, could be overcome.

(b) The region of Cerro de Pasco, already famous for its silver, lead, and coal mines, possesses the richest copper deposits of the whole country. Composed of chalcosine, chalcopryite, bornanite, etc., they contain sometimes as much as 60 per cent., the average being 40 per cent. There is little doubt that these deposits will in the near future play a great role in the mining industries of Peru. These deposits have recently been closely examined by Mr. Michael Fort, Professor at the Mining School, of Lima. The conditions for the exploitation of these deposits are quite different from those existing in the Ica districts; fuel and water are abundant, and the distance (which can be covered in two days and a half on horseback) which separates Cerro de Pasco from the railway of Callao to Oroya will soon cease to be an obstacle as this railway will be extended to the great mining center.

(c) The deposits of Yauli and Morococha (13,200 feet altitude) rank second only as far as productive importance is concerned. For the same reason as those of Ica these mines were abandoned to give way to the exclusive working of silver deposits. Today, with the increasing copper prices, the exploitation has again become lucrative. The richness of poor ore is here from 10 to 15 per cent.; this ore is sold at a low price to the great establishment of Casapalca, as they cannot afford any high transportation. However, the general opinion prevails that if these ores were worked by the fusion process, on the spot, even veins containing 8 per cent. could be exploited successfully.

We may also mention in connection with these deposits those of Acari in the province of Camana. The trials made there, however, by "The Acari Copper Mining Syndicate, Limited," are said not to have given satisfactory results.

Be this as it may, a certain number of Peruvian and foreign engineers are now studying, on the spot, the copper deposits in this district.

Tin.—Many people have been investigating the tin deposits in Peru, though tin occurs only in small and unimportant deposits. In 1898 the total exports of tin did not amount to more than about 2 tons, which were shipped via the port of Mollendo. Bolivia, however, has considerable tin deposits.

Magnesium.—On the coast of Peru a number of good and marketable magnesium salts are found, amongst which the sulphate of magnesium (Epsom salt) is the best known. The deposits are, however, little worked.

Manganese occurs in many districts of Peru, but it is chiefly associated with copper, silver, lead, antimony, and iron ore. The deposits, as a rule, are not extensive, and therefore the output is very inconsiderable.

Mercury and Cinnabar.—Peru, which in former times produced large quantities of native mercury, does not export any quantities worth mentioning, though there exist considerable veins whose length is estimated at at least 200 miles.

The celebrated mines of Santa Barbara, in the neighborhood of Huancavelica, alone produced, in the period from 1571 to 1813, more than 5,000 tons, representing a value of 75,000,000 pesos gold. In spite of the land slips which have occurred since work in these mines was abandoned it is estimated that this plant could still furnish large quantities of cinnabar for many coming decades.

The mines of Chouta, situated at a height of 15,762 feet above the level of the sea, in the province of Huanuco, mines which also were abandoned many years ago, produced an average of 14 tons a year. It is, therefore, strange to see Peru importing annually considerable quantities of mercury from Great Britain when there are such large deposits in the country itself.

Nickel.—This metal occurs chiefly in the province of La Mar, in quantities sufficient to warrant a successful exploitation. Means of communication between this province and the coast must, however, be improved before these deposits can be profitably worked.

Gold.—A story of the quartz and the auriferous washings annually exploited would fill too many columns. There is really no province in Peru where there may not be found, not only traces, but mines or important washings of this precious metal. The same as for copper, the regions of old signalized as containing auriferous minerals are today the aim of capitalists. Every day new mines are claimed according to law, and several Peruvian and foreign companies have recently been formed for exploiting the auriferous quartz deposits of Carabaya and of Sandia and the washings of Inambari. It is calculated that the total production of gold, which amounted to about 1,562 pounds in 1897, reached about 2,000 pounds in 1898.

A French engineer, who, some months ago, visited the Fair of Cojata, said that the representatives of the business houses of Arequipa had not money enough to buy all the gold which was offered by the "Puchiris" (Indian Gold Hunters).

Petroleum.—This mineral oil exists in large quantities and rich deposits in the province of Piura. The opinion even prevails in Peru that this petroleum is superior to that found in the United States, that it has less odor, and that it contains relatively little paraffin. It also is said that it gives a splendid light. The production increases every year considerably. At present several hundred wells are worked, and in 1898 the total production of petroleum amounted to more than 745,000 gallons, which means an increase of 45 per cent. within one year.

Several foreign companies are engaged in the exploitation of these petroleum fields. Prominent amongst these is the Italian Piaggio Co., which is doing very well. The French South American Petroleum Co., which is also established in the above-mentioned province, has not had such good results as the Italian company.

Asphaltum and Bitumen are also found in the provinces of Peru, and small quantities are exported to the neighboring republics.

Phosphates.—These salts, which are now so largely used for agricultural purposes, have been the object of the closest study of the Peruvian Government for the last two years, and it is said that considerable deposits occur in the neighborhood of Ica, and especially in the Pampas of Ocuja, though they have not been worked to any extent so far.

Lead.—This mineral is chiefly associated with silver and antimony, and is, perhaps, the most abundant of all the minerals which are found in Peru. In 1898 over 8 tons of lead were exported to Ecuador, and a quantity of about 837 tons of argentiferous lead was exported to the markets of Europe and the United States.

Salt.—The exploitation of the salt mines and salines is since three years controlled by the government. The revenue amounts to about 1,000,000 pesos. Rock salt mines occur in the provinces

of the north and south, and also in the central provinces. The "Cerro de la Sal," in the province of Junin, has for a long time been exploited by savage tribes who live still in that district. The annual production is estimated from 30,000,000 to 40,000,000 pounds. The greater part of this is consumed in the country, and only small quantities have so far been sent to the Argentine Republic and to Colombia. The latter republic, in 1898, received about 120 tons.

Sulphur.—Sulphur deposits are found in the neighborhood of all the volcanoes, and also in many other districts, especially in the neighborhood of Tumbes, in the province of Piura. The principal veins occur in the neighborhood of Sechura, in the same province. They embrace a large number of veins whose thickness varies from 1 to 20 feet. They contain from 52 to 70 per cent. of sulphur. The district, however, where these veins are situated, is an absolute desert.

In order to enable the exploitation of these sulphur beds it would be necessary to construct at least a narrow-gauge railway line about 25 miles in length to the port of Salinas.

Before concluding our remarks on the mineral industries of Peru we have still to mention marble and mineral waters.

Marble of a very good quality occurs in many districts, and during the last two years it has been worked on a larger scale than ever before.

Mineral-water springs occur especially in the south of Peru, where the greatest number of volcanoes are situated. The mineral waters of Yura are principally appreciated by foreigners, who use them as table waters. The exportation of these waters to the neighboring countries of Peru has also been started. Last year a new company was formed to exploit more commercially these water deposits. In the Province of Ica one encounters also marvelous springs of sulphuric waters, and quite a number of bathing places have been established there of late.

The Lapidary Industry of Birkenfeld.

The cutting and polishing of precious and half-precious stones forms the chief industry of the little principality of Birkenfeld, up among the hills of the Nahe River, and gives employment to over 5,000 persons.

Although an improved factory system is gradually superseding the laborious methods of former times, there are nevertheless plenty of the old polishing and cutting works, which bear evidence to the lives sacrificed to this industry.

In the early days of the trade, agate quarries existed in the near-by hills, and this half-precious stone was cut and polished by a very laborious method, which is still practiced, although the agate quarries have long been exhausted and the raw material—as well as amethyst, jasper, opal, topaz, etc.—has been imported (since about 1834), chiefly from Brazil, whence it is shipped to this out-of-the-way place to be cut, shaped, and polished for the jewelry trade.

The usual method employed in cutting and polishing these stones is the following: In a rude hut by a stream, which furnishes the power, four large grindstones about 4 feet in diameter are so fixed that their axes are only about 1 foot above the floor, into which a slit is cut, so that part of the grindstone is below its level. This lower portion passes through the water, thus keeping the stones constantly wet.

The operator has a bench or block of wood about 18 inches high, hollowed out to receive his chest and body. On this bench he lies at full length, and with his fingers holds the small piece of opal, amethyst, or other stone which is to be cut, against the grindstone, slightly above the level of the floor. In this position the men lie from morning to night, day after day. Consumption usually carries them off at an early age, but other men are found to follow this vocation, as the earnings are comparatively high. The operator usually owns his grindstone, or at least half of one. This represents an investment of about \$500, and a skillful lapidary can earn from \$15 to \$25 per week. He does not usually cut and polish stones on his own account, but generally contracts with manufacturing jewelers, who furnish him the stones in the rough, to cut and polish at a certain price per gram. As the stones, even in the rough, represent quite an outlay of money, the honesty of the workman must be greatly relied upon, for nobody can say in advance how many grams of finished stones a certain piece of opal, amethyst, or the like may yield.

Besides these half-precious stones, precious stones such as diamonds, etc., are also cut and polished there; but this is an entirely different branch of the industry and is chiefly carried on in factories with modern machinery. Another branch of the industry in these parts is the cutting of cameos.

Pearls are also polished, drilled, and cut and shipped in large quantities to all countries, including the United States, invoices covering single shipments of the value of \$60,000 having been certified to at the consulate at Mainz.—U. S. Consular Reports.

RIB DRAWING WITH MACHINES.

A Proposed New Method of Mining Coal by the Use of Longwall Undercutting Machines for Taking Out the Rib.

By W. S. Gresley, Mining Engineer, Erie, Pa.

By this method, the ribs, as planned and formed in the mine, will take the shape of blocks or pillars, becoming ribs in fact only as they are reduced in size by a special method of working. Using the old word rib, however, what follows will probably be better understood and appreciated by the mine official and the practical coal miner than the term pillar, which, in room-and-pillar systems usually refers to the chain or entry pillars and to stumps.

The new plan is to apply more particularly to seams of coal that contain considerable refuse, the Pittsburgh "thin vein" for example, and those with good roofs, and it aims at abolishing pick work as far as possible, namely, to undermine or cut the ribs with machines from one end to the other. To accomplish this, the breast type of machine is not to be used, neither is the puncher, or pick type contemplated unless experience, test, or circumstances shall demand the one or the other, but it is the longwall type that, if I mistake not, is going to do it.

Let the entries, rooms, and the narrow work be cut with the machines now in vogue; and, having formed or blocked out the ribs separating the rooms, take slice after slice (skip after skip) off them, using a longwall machine for the purpose in the manner suggested below. Now, by the plan in question, the ribs are to comprise the largest proportion of the coal to be worked, so that instead of having the rooms wider than the ribs the latter will be the wider: perhaps the ribs will be two-thirds (66 per cent.) of the whole. With this object in view, and since the longwall machine under favorable conditions cuts very much more coal than the breast or puncher type, the anticipated result, if secured, should be a decided gain to the coal operator.

The operation or problem then, as I have thought it out, would be about as follows:

First.—Drive the productive or butt entries as wide as practicable, and say three of them in parallel (making a 3-entry system of it) to the limiting line of the section or district to be worked by the new method. Gob the slate and refuse if possible, piling some up where least likely to hinder the future or the second stage of the machine work, and try to avoid turning any rooms until the entries are up their distance.

Second.—Turn rooms their full width (why have any necks?) off the flanking entries (see *x* and *z* Fig. 1), beginning along the

line or boundary, and on both sides if the coal is flat, but on the rise side only if there is too much dip. These rooms, numbered 1, 2, 3, 4, 5, 6, etc., on the plan, must be worked on sights and kept straight and of uniform width; also the slate and refuse is to be placed on the side shown; the position of the track being nearer to one rib than the other (see thick dotted lines in rooms numbered 5 and 6).

Third.—Cut over between the heads of the rooms, casting the rubbish against the boundary, not against the ribs. The ribs, say *A* to *F*, will then be ready to start upon.

Fourth.—To take out the ribs. This work is intended to be done all in one direction, namely, retreating or outwards, i. e., the ribs on the right hand of the entries are to be worked off on the right hand of each room, those on the left hand (on entry *x*) to come out towards the left hand; and in this way to leave all

gob, falls, and caves behind as the rib drawing proceeds. This method then provides for taking out the ribs on the butt of the coal, or end on, where the seam is pronouncedly cleated, faced, or jointed. The rib-cutting machines are to travel along the sides of the ribs, cutting while traveling, from one end to the other. The cuts or runs referred to are indicated by parallel dotted lines upon the ribs marked *A*, *B*, *C*, *D*, etc., and the successive slices or skips of coal to be undercut and removed one after another are marked respectively 1, 2, 3, 4, 5, 6, etc., upon those ribs. The number of slices to come off each rib, of course, will depend upon the width of the ribs, the width of the cuts, and the width of the remains of the rib that may be found to be unworkable. Whether the machine cut be made going up the room or coming out thereof, is immaterial, the object is to get the full length of the rib undercut so that when the sprags, or other

Fig. 1. Plan

Section on Line C B.

FIG. 2.

timber supports to the face are knocked out, the coal is free to fall, or to be taken down; and then broken up, cleaned, and loaded out. As each successive skip or slice of coal is cut and removed from a rib, the track is moved over a few feet nearer the working face and the posting brought up as closely as possible to the cars standing upon the track. In room number 5 five cars are shown distributed along the face of the rib ready to be loaded with coal coming off slice number 3 of rib *C*. As to the method or system to be practiced in the rib drawing, the first rib, marked *A*, should, I think, be pretty well reduced before the second one, rib *B*, is commenced, and the third rib *C* should not be started until, say *A* is about finished and *B* well under way; but actual practice will be our best teacher. Anyway, the quicker these ribs are worked out the better will the result be. And of course the ribs on both entries should be drawn simultaneously and come out evenly: likewise the entry pillars, bringing up the rear. Perhaps the longwall cutters may

be used to advantage on these pillars by slicing them up longitudinally—on the face.

Fifth.—In this way then each rib will get narrower and therefore weaker as each skip is taken off it. The last few skips will be the critical ones—the real test of this method, especially so when several adjacent ribs in each range are coming out together, and when the first weight or the fall over the gob has been felt. And this point brings us to the question, namely, How do I propose to hold up the roof over the working faces in the ribs, or, in other words, how are the rooms to be kept open and safe to work in until the ribs are out or as much of them as possible, pulled? My answer is this: I do not claim to be able to take out all of the rib coal; in my opinion from 3 feet to 5 feet in width and the length of the rib will have to be left, partly for the reason that the last strip or shell of a rib will become too much weighted or crushed to work, and partly to serve as a protection to the next rib or room in advance of it. The idea that I have in mind in this connection is to make this last thin wall or shell of rib coal next to the gob of the adjoining room serve as a temporary support to the roof while the places are being worked, but as soon as finished, abandoned; it will have served its purpose and collapse, thus letting the top, the cover, settle down upon the worked-out area. The last few feet of rib we have just been speaking about is shown in Fig. 1, rib marked A, between slice or skip numbered 9 and the gob in room number 2. Of course in some cases wider strips of the ribs may be required to be left; in others, little or none need be lost. But in addition to this narrow shell next to the gob of the room ahead of it, my idea includes, if indeed it does not demand, caring for the slate and refuse taken down or made in the working places. This refuse and slate then, is to be systematically piled up from floor to roof in such manner as will best carry or support the same and steady the top during the removal of the ribs. To this end then, the slate and dirt produced in driving rooms—heading-out the ribs as we may fairly regard it—is to be dealt with so as to give as much lateral support to the ribs as possible, as well as help the posts hold up the roof. Perhaps the greatest use to which the refuse could be put will be secured if the stuff is built up as solid as possible into pillars or isolated blocks, which, as the rib drawing proceeds, shall be extended or take the form of wide walls somewhat in shape as sketched in plan (Fig. 1), room 1 and rib A; but to make these heaps of refuse of any real use they must be well built and built right up to the roof. The more thorough and systematic this pack building is done, the less coal will be wasted in rib pulling and the greater should be the saving in timber. Of course, the amount of coal it will be impossible to save in the drawing of ribs will depend to some extent on the depth of the mine, the strength of the seam, and other factors.

Doing the undercutting, with machines, it will be very important to keep the weight off the ribs, for the last few cuts in them especially, and much skill and judgment will be needed in regulating and superintending this work and that pertaining to the use and distribution of the debris, and more particularly the timbering and timber drawing of the places.

Referring again to the matter of reducing the ribs to their narrowest dimensions; in other words, of minimizing loss of coal, an inspection of the rooms and ribs marked, respectively, 1 and 2 and A and B on Fig. 1, will show that the narrower the rib becomes, the greater grows the area of support derived from the piled-up refuse, to say nothing about the posts, which, for the sake of clearness, have been left out of the figure. Particular attention is directed to this point in the system, for the reason that although the area of solid coal remaining is small it probably possesses great resistance to crushing or squeeze since it is well supported in front by large and heavy and solid piles of slate, etc., while back of it stand say two rows of posts, and these posts again are backed up by stout piles of slate. With all this precaution, it seems to me that the loss of coal in ribs would be quite light, and the chances of losing valuable material in them, very small.

Sixth.—What the width of the blocks of coal separating the rooms—the ribs—ought to be, is a matter more for trial and experiment than to be discussed here. The wider the better, I would suppose, provided the loss of coal can be kept within reasonable limits and the working places maintained. The best length also is a matter not to be overlooked.

Seventh.—If the method here outlined were given a fair test and resulted favorably, it is easy to see that a very economical system of car distribution and gathering might be arranged. The empties could go up and be left in one room or rib and the mule and driver pass on and down the next place, taking the loads out onto the entry. Many more men could be put to work in a very much smaller area of working places than is at present possible, thus concentrating the work and mining the coal much faster. A considerable saving in posts might result, and there would be fewer workings and less entry, etc. to maintain.

Eighth.—Of course nothing short of an actual test of this plan can decide as to its merits or demerits and determine its relative economy with present practice. The idea was explained to two very practical men, and both were so desirous of giving it a trial that the writer persuaded the operator to order the longwall machine for the rib work, but before the work could be started the mine changed hands, and, although the machine was built, the matter has probably been dropped.

As to the records of longwall mining machines, it may be remarked here that there are three or four kinds or types on the market, and that each has made a good showing and done good work under varying and favorable conditions in Illinois, Iowa, Missouri, Indian Territory, and elsewhere. To get best results from them, the ends of the ribs or pillars should be left free or clear of refuse; straight faces to cut; and faces as long as possible; with every facility for transportation from one rib to another in order to minimize loss of time.

Ninth.—Dimensions have purposely been omitted from the plan, Fig. 1, because if anybody wants to try the method he should lay out the work to suit the circumstances and conditions of his seam and his mine. The plan is one offering many points for profitable study and discussion. I offer it, not as a cut-and-dried method or all theory, but as an idea—a new one, I believe, worth something more than a passing notice, to be read and then shelved. It seems to me, that in this age of coal cutting by machinery, and so long as our existing room-and-pillar method in machine mines holds sway, the loss of merchantable coal in ribs and pillars will not be materially reduced until the latter can be pulled with machines as cheaply as, or cheaper than, room coal is produced.

The writer has seen a great deal of longwall work, both by the advancing and the retreating plans. The method of drawing the ribs herein sketched, comes under the latter plan. He has also watched longwall undercutting by machines, and after 10 years' experience in the charge of room-and-pillar mines, he may, perhaps, be considered to know what he is talking about in this connection. The pages of this journal are doubtless open to receive and print comments and criticisms of practical men having something to say or writing for further details.

[The pages of MINES AND MINERALS are always open for the presentation of new ideas like those contained in Mr. Grealey's article, and for discussions and criticisms of the same.—EDITOR.]

P. & B. Products.

The Frank S. De Ronde Co., 52 and 54 John St., New York, is the sole distributing agent for all the products manufactured by the Standard Paint Co., of New York City, for many years makers of the well known P. & B. products. This agency covers all the

eastern part of Pennsylvania, etc., a full stock of these products is carried at the Philadelphia warehouse, from where prompt shipments can be made. More than 14 years of practical use have demonstrated the fact that the P. & B. paint is an excellent preparation for use in and about mines. Being free from tar and oil the makers claim that it will not evaporate, chip and peel off like the ordinary asphalt and oil preparations. It possesses extreme elastic properties, is very penetrating and being unaffected by the action of acids and alkalies, gases, fumes, and especially mine water, is particularly well adapted for coating all kinds of iron work about mines, such as pipes, pumps, screens, etc. The Frank S. De Ronde Co. is willing to send samples of this paint free of charge to any mine owners who may be interested. The Ruberoid Roofing made by the same company will certainly interest all connected with mines. The enormous strides made in the sale of this material in the past eight years is almost beyond belief. It is now in general use the world over by thousands of the largest consumers and manufacturers. Enormous quantities are consumed by such well known concerns as the Repauno Chemical Co., Wilmington, Del., New York and Pennsylvania Co., Lock Haven, Pa., as well as many of the large coal mines throughout Pennsylvania, and almost every railroad in the country. Ruberoid is not a paper roof, having as a base the best of wool and hair felt, thoroughly impregnated with the water and acid proof composition. It will not run at any heat and is guaranteed in every particular. The makers would be pleased to send samples and the names of dozens of well known users to all those who may be interested. Correspondence is invited by the makers of these well-known products, and mine superintendents needing paint or roofing will undoubtedly find it to their advantage to correspond with the Frank S. De Ronde Co. The trademark illustrated herewith is a striking one, and it will be found on all goods sent out from these factories.

ROCK DETERMINATION.

The Western Editor of MINES AND MINERALS will, without charge, examine and name, so far as possible, samples of rock sent him, the answers being sent by postal card to the sender of the specimen. He will only undertake to name average rocks, such as can be fairly determined at sight; and microscopic or chemical analyses will not be attempted; neither is it always possible to determine with absolute precision and certainty a small sample, or one decomposed and oxidized, and with such samples the sender must be content with the provisional determination that it *APPEARS* like such and such a rock.

Questions involving an opinion on mining property, for which an expert would be entitled to a fee, will not be answered, but advice that will aid the prospector will be given.

The following conditions must be observed by those sending specimens for determination:

The specimens should be fresh and about 2 inches square.

Each should be distinctly labeled.

The name and address of the sender, written very distinctly, must be enclosed in the package.

The package should be sent prepaid to Prof. Arthur Lakes, Room 608 Boston Building, Denver, Col.

A letter should accompany the specimens describing the locality, mode of occurrence of the rock and other facts, and rough sketches may accompany such descriptions.

Samples will not be returned unless by request, and where stamps are enclosed to cover postage or expressage and cost of packing.

Example of the Granitic Series in the Field.

Let us take as an example what we may see of granitic rocks in almost any cañon in the Front Range of the Rockies. At the entrance of the cañon we find the sedimentary rocks of the Paleozoic series of quartzites or limestones uptilted and resting upon the eroded edges of the granite; tilted usually in a contrary direction to that of the sedimentaries, so the latter rest unconformably on the former. It is very clear that here we have the old original granite island that was upraised, folded, crumpled, tilted, and eroded by ancient seas which laid down their sediments upon the battered, broken, wave-worn bases of the granite cliffs, as seas are doing nowadays against the bases of granite cliffs in our sandy bays.

The uptilted character of the stratified sedimentaries shows that after they were laid down along the shores and cliffs of the granite islands, of course horizontally, the granite island and nucleus must have taken a second rise of several thousand feet, at a later period, and carried up along its flanks and tilted sometimes to verticality the beds reposing at its base from Cambro-Silurian to Upper Cretaceous. Now all such mountain movements involve great crumpling and folding of the granite mass. First it was crumpled and folded up to rise above the ancient sea as island forms, and then the already crumpled, fissured, folded mass was again crumpled, fissured, and folded to assume mountain forms.

Granites often break up along the joint planes, giving a cliff a masonry-like appearance, as shown in Fig. 1.

Is it any wonder then that when we enter the cañon and pass into the bowels of the mountain and study the great ribs of which it is built, that we find the whole granitic series a mass of intricate crumples, foldings, fissurings, fractures, and cross-fractures,

FIG. 1. GRANITE CLIFFS.

mingled with all sorts of evidence of aqueo-igneous heat and fusion, developed perhaps in part by these movements, and see on all sides of us great dike-like veins of feldspar and quartz, the matter of the rocks that has boiled over, from great veins 100 feet wide, traversing the cañon walls like broad ribbons, or in dike-like walls, down to tiny little veinlets, whose intricate puckerings we can span between finger and thumb. A moment's glance convinces us that whatever was the remote origin of the granitic series, it has evidently been once in a semiplastic condition and under inconceivable pressure, for in the first place, no rocks in a

rigid condition could be thus puckered up and folded like pieces of cloth without a multiplicity of fractures taking place both great and small; and secondly, no such folding and puckering could have been produced without the agency of inconceivable pressure, more or less laterally applied, producing the great arches forming the mountain ranges, as well as the tiny puckerings forming the detail of the rocks.

In many of our cañons, the class of granitic rocks we meet with on the flanks of the mountains and for a long way up the cañon are liable to be laminated and contorted schists and bedded gneisses. We rarely meet solid amorphous granite till we have

penetrated into the core of the range. The schists are conspicuous by their laminated structures, by their being composed principally of mica, or hornblende, and except when formed of white mica, or muscovite, by their dark color. They are generally contorted and puckered up into intricate folds, the form of which is often delineated by veinlets of pink feldspar and quartz following the course of the folds and giving the rock a beautiful marbled and banded appearance. Sometimes we find narrow lenses of quartz and feldspar following in a chain-like belt alternately opening and closing, showing that one contorted wall of schist was forced up past the other, bringing convexities opposite convexities, and concavities opposite concavities, as exemplified by tearing a sheet of paper in half and then placing the two pieces together again, only moving one half of the sheet up or down a little.

These irregular pockets and pinches are miniature forms of what we often find in ore deposits and due to the same movement. From these little segregative-interstitial veinings, pockets, and blotches in the schists, we may presently come upon much larger vein or dike-like masses, composed of very coarse feldspar and quartz, with usually but little mica, traversing the rocks. In many cases we find no absolute dividing line between these pegmatitic veins and adjacent rock, no "walls," so to speak; the quartz and feldspar seem to be closely welded to, and part of, the surrounding gray country rock (see Fig. 1) as when we cut a finger and the wound grows sore from bad blood and fills with matter, and finally leaves a white line where the old wound used to be. You could not pick out that white matter from your finger and leave the walls of flesh clear on either side. No more could you pick out the white feldspar and quartz that have healed these weak places and wounds in the rocks and leave the walls clean on either side. It seems just as in your finger, that a wound, or weak place was formed, and as blood and matter pour in from the flesh to fill that wound, so the material of the country rock composed of quartz and feldspar came in, or was segregated in, to heal the wound or weak place formed by movement in the plastic mass, and there finding greater room and expanse, crystallized out in a more coarse and sparry form than the adjacent country rock.

These might perhaps be given the name of so-called "segregative veins," the material being derived, collected, and gathered out from the material of adjacent wall rock. They are really coarse, sparry, granite veins in granitic rock. Again we find other bodies that seem to have filled a well defined, and perhaps open, fissure, the line of demarcation being very distinct between wall and vein, and even sometimes with crevices between vein matter and wall.

This would look to us like a fissure filled by material rising from below rather than filled from matter from the immediately adjacent wall. Be it however as it may, it is nothing but a vein of sparry granite in granite. These latter are most of our ore-producing veins of the granitic regions, such as those of Clear Creek, Gilpin, and Boulder counties.

From the laminated schists we pass to an intermediate series of banded and sometimes contorted gneisses, too solid massive to be called laminated schists, yet showing a banded and sometimes contorted arrangement of the layers of mica and feldspar, not unlike the schists containing also more quartz and feldspar.

From these again we pass to the heavy bedded granite gneisses, a piece of which, in a hand specimen, we would call granite but which in the field shows a distinct heavy bedded structure, different from the definition of true granites, which are generally supposed to be massive, like lump sugar, and to be more or less structureless.

Algonkian Gneisses and Schists.—In South Boulder Cañon, and in several localities in Colorado, we find on the flanks of the true Archaean series of granite rocks what appears to be a later series

FIG. 2. BEDDED GNEISSES AND SCHISTS.

called the Algonkian. It consists of bedded gneisses, quartzites, and white mica schists. The bedded gneisses are full of white blotches, flattened and elliptical, which seem to be the metamorphosed relics of the ancient water-worn quartz pebbles, of which the original rock was formed before it was metamorphosed into a gneissic crystalline condition (Fig. 2).

As regards the schist we appear to observe that by compression and greater metamorphic action, the loose leaves of schist are bound up into the volumes we are apt to call gneiss. Blotches of iron occur in these sericite schists which, with greater metamorphic heat develop into garnets forming a garnetiferous gneiss, and gneiss by greater aqueo-igneous heat and metamorphic action may pass into true amorphous granite.

Granite as a Mining Rock.—As a series for containing veins carrying precious ores, as well as baser ones, the granitic series is notorious. Most of the fissure veins carrying gold and silver are in this class of rocks. Lead, copper, zinc, and iron also occur abundantly. Granite has been thought by some to be the parent rock of gold, the original matrix whence the gold came. Gold is not only found in place in veins in granite, but, at times, diffused through the rock itself.

A striking example of this is in the coarse, red feldspathic granite forming the wall rock of the noted Independence mine at Cripple Creek, Col. By ascending hot mineralizing and acid waters the granite has been robbed of some of its decomposable elements; the dark micas or hornblendes have been oxidized out and replaced by gold-bearing tellurides. This granite has sometimes been so much disintegrated of its oxidizable constituents that it almost falls to pieces in a mass of quartz sand. The decomposed granite is shipped wholesale as ore from a zone of many feet in width.

Besides occurring in so-called quartz or rather pegmatite veins in granite, gold is doubtless more or less distributed through the great masses of granite; and the rivers, the world over, that show "colors" in their sands have largely derived these, more from the general breaking up and disintegration of mountains of granite than from gold-bearing veins in the granite. In the veins the gold may be concentrated, whilst it may be minutely diffused through the mass of the rock.

ECONOMY IN MANUFACTURE

Of Mining Machinery—Its Importance to Purchasers—The Elements of Costs and How They are Determined.

By Charles H. Fitch.*

The elements of cost in mining machinery are complex, and as sundry of them are commonly estimated as proportional to others, any change in the latter is multiplied in the aggregate like an extension of lazy tongs.

The basal elements are weight and value of materials (to which a small percentage of cost is added for warehousing), and time and rate of labor. These are obtained for every considerable portion of every job, by the use of cards sent out to the shops from the office, and returned with the required data. These cards are a great convenience. A pack of them girt by a rubber band is the shop record of basal elements of cost on a given job.

In the factory office, clerks transcribe the card values of labor and materials upon broad cost sheets with tabular rulings. To these sheets pinned together as folios the selling correspondent resorts in fixing the figure which he asks the mining man to pay for the machinery.

These figures, however, necessarily include other costs and expenses of a general character not belonging to any particular job. Such expenses are called burdens, and are taken off from time to time to establish the ratios which they bear to the aggregate of assignable costs.

The foundry, smithy, machine shop, etc., each has its separate burden. Above these is the burden of office expense, management, advertising, selling, shipping, and reasonable profits of business, if any. These constitute additions to the price, none of which the customer ought to escape.

In manufacture, as in mining, labor is the most important basal element, but its cost does not form so large a part of the value of product in manufacture as in mining.

In the foundry, costs of materials, supplies, and other expenses, usually exceed cost of labor, and this fact makes the foundry a specially promising mine for economy of administration. Small details of buying and use assume handsome aggregates in the course of a year, and should enable a painstaking economist, with proper recognition and authority, to earn a good salary in many of our large general foundries, and at the same time provide a good extra profit for his employers, that is, if their competitors

do not get equally clever and devoted men, economize in their foundries, and then cut prices to correspond in the selling.

The mining product is staple and its price is fixed by market conditions, but the machine factory product has an elastic value, and is multiform in specification. The mine manager has a consistent and one-sided problem—to reduce cost of production, and so leave a larger margin of profit. The works manager has a double problem, to be economical in production and also liberal to his own interest in selling. His profit is not a natural find. It is grudged him on both sides, by the workman with whom he economizes, and by the customer who would like to economize with him, and is able to do so when competition eliminates the capital value of his betterments, and tends to leave him with no rewards but those due to a higher form of skilled labor.

Not a few highly-organized shops making engines, machine tools, and other fine machinery are poor dividend payers. Especially do those shops fail to pay dividends in which the stock-holding interests are partly alienated. If two party interests become alienated the majority in control does not relish paying tribute on a large block of minority stock, but would prefer to divert the dividends to betterments and large salaries to preferred persons in executive places. With such persons dominating the office end of a works, liberality rather than economy is the rule of service. Privilege and favor leak down, sinecures are allowed and become patterns to subordinates. The enthusiasm for economy is impaired by practices distinctly opposed to it, and held in higher favor. It is seen that there is not one rule for all, and the effort for economy becomes more perfunctory than strenuous in those of whom it is expected.

The manufacturer locates himself in a nest of accumulating expenses which build about and hinder his growth. If he expands to employ a city he is taxed on city values, and must pay unearned increments out of earnings. He has not the bulwark and advantage of the mine operator in possessing a bank of found value to draw upon. To share this advantage the factory must enter into partnership with the mine, and in such a union it is the mine which will have the capitalistic and potential preponderance. Although one man or company may control both, it is the mine which will in effect employ the factory, and pay dividends. This will happen when factory processes are completely economized, and there is no liberal margin left in the business.

Systematic economy is not easy to realize. In the large manufacturing shop, building to contract, character of work is varied and changing. With continual change of conditions there is difficulty in making comparative checks upon efficiency. On the other side the selling is influenced by favor and personal prejudice, by wide variations in specifications, and in claims of merit, specious or real, and by premiums on time delivery due to the improvidence of users of mining machinery. Among these vicissitudes system and economy are evasive, and are not easily corralled.

Despite its difficulties of attainment the manufacturer pursues, and is obliged to pursue, systematic economy, and making virtue of necessity proclaims the customer to be a sharer in his saving. But if, as would appear, the competitive chasing of such economy tends to thin his profits to the breaking point, it is a pursuit akin to the "Hunting of the Snark," in which Lewis Carroll satirizes all forms of futile and impracticable propaganda. One of the hunters of this mysterious creature is described as finding it, and simultaneously disappears, whereat the poet observes:

"But beware if the Snark be a Booby, for then
You will swiftly and silently vanish away,
And never be heard from again."

With this peril in view, if the contagion of *economy* is to infect our profits we do not care to pursue it with inconsiderate zeal.

But the mining man is expected to have no such scruples in behalf of the manufacturer. Let him look to his own economic interests, now much neglected. His societies can exist to no better purpose than to specify that which is finest for his purposes, avoiding improvidence, the heresy of cheapness which is not economical, and ancient and freakish features of machinery which are not to the best purpose.

If the first cost of what is best is now formidable it is largely due to the improvidence of the mining man. Let him essay the task of specifying the best, and making his specifications standard. Then the manufacturing effort now spent in catering to meaningless and uneconomical variations will be confined to more uniform lines. Manufacturers can and will then produce the best at much less cost than now for two reasons:

1. There will be removed an element of uncertainty in the selling, which now greatly increases prices.

2. The problem of shop work will be presented in its most advantageous economic form, namely: The repeated production of one kind of work to which a man can give his undisturbed attention until it is unerringly accomplished in the best way.

EXAMINATION QUESTIONS

For

Mine Managers, Mine Foremen, Fire Bosses, Etc.

EDITED BY J. T. BEARD, C. E., E. M.

Many of the questions given by the several State Boards of Examiners suggest principles which can be more satisfactorily discussed in a separate article than is advisable in an answer to an examination question, which should be as brief and concise as possible. It is the purpose of MINES AND MINERALS, to discuss in this department of "Examination Questions" the principles of practical mining upon which these questions are based, feeling sure that such articles will be appreciated by and be a help to all who are preparing themselves for mine examinations.

Mine Inspectors' Oral Examination, Held at Des Moines, Iowa, March 7, 1900.

QUES. 1.—If appointed State Mine Inspector, how would you proceed to make your first examination of a mine?

ANS.—I would proceed to the mine, make myself acquainted with the mine officials, and after a brief inspection of the mine maps in the office, I would proceed at once to examine minutely and in detail the equipment at the surface. I would begin at the engine room, examine the engine, take notice of its style and manner of working, and particularly of the brake controlling the motion of the drum. I would converse briefly with the engineer in charge, and would then proceed to examine the boilers and fittings. I would next proceed to the shaft and examine carefully the hoisting ropes, cages, wings, safety catches, gates, and other appliances. Before going into the mine, I would examine carefully the ventilating apparatus, if this were at the surface, making note in my memorandum book of the speed of the fan, its size, and whether the same was an exhaust or a blow-down fan. I would desire the engineer to lower me slowly into the shaft, giving me an opportunity to examine the shaft lining as I descended; I would observe carefully the working of the cage in the shaft, the signals given at the upper and lower landings, as well as the signals given in response by the engineer. I would examine carefully the bottom of the shaft, its timbering, the arrangement of tracks, and the manner of handling the cars. I would notice if there was provided a proper manway around the shaft, and would next proceed to the intake airway or the foot of the downcast shaft. Having carefully observed here if the speed of the fan, as ascertained by counting its pulsations, was the same as it was when I was at the surface, I would select a suitable place in the airway, not far from the foot of the downcast, and having measured the size of the airway at this point, I would as carefully as possible obtain an average reading of the anemometer at that point of the airway; and would make a memorandum of the same in a book carried for the purpose, being careful to note also the correct date of my visit. I would then proceed inbye upon the intake airway, observing the character of the stoppings, timbering, and the general condition of the air course. I would examine also every door, overcast, or brattice upon my way, as I followed the air on its course through the mine. I would, from time to time, measure the air at different points in the airway, and ascertain if the full amount of air was passing. This would show whether the doors, stoppings, bridges, etc. were air-tight, or if the air was leaking at any point. I would measure the quantity of air going in each split at the mouth of the split. I would measure the air also at the inside breakthrough of each split, and would see that these breakthroughs were all of a proper size, and were free from any incumbrances such as tool boxes, powder kegs, etc. I would go to the face of the rooms and examine carefully the condition of the working face; the amount of timber and caps on hand in the several rooms and working places. I would talk with the men, giving them a fair opportunity for making any suggestions whereby, in their opinion, the general conduct of the mine might be improved. I would further examine all airways and haulage roads with respect to their size, timbering, drainage, and general arrangements. Returning to the bottom of the shaft, I would examine carefully the pumps, and inform myself particularly in regard to the efficiency of the drainage system of the entire mine.

QUES. 2.—Explain how the condition of the weather and direction of the wind may affect the production of gases in coal mines?

ANS.—Whatever conditions operate at the surface to alter the ventilating pressure in the airways of a mine, affect at once the amount of gas issuing from the old or abandoned workings. A fall of barometric pressure is felt very soon in the mine workings, and the gases contained in the old rooms and abandoned places of the mine expand in proportion to this fall of pressure, and flow out upon the airways, where they mingle with the air current of the mine. A strong surface wind may also produce a fall of ventilating pressure, if it acts directly to oppose the current dis-

charging from the upcast of the mine. In gaseous mines, there is always an increase in the gas issuing from the coal or from feeders in the mine, whenever there is a fall of barometric pressure. It has generally been observed that the fall of barometric pressure precedes the effect in the mine, by from two to three hours, and thus gives a sufficient warning to provide against the increase of gas which is sure to follow.

QUES. 3.—What precautions should be taken in entering an abandoned mine?

ANS.—The precautions necessary to be taken in entering an abandoned mine relate particularly to the condition of the mine with respect to gases. In Iowa, this danger relates particularly to the presence of blackdamp or carbonic-acid gas (CO_2), or whitedamp, carbonic-oxide gas (CO), since there is very little, if any, marsh gas in the coal seams of this State. The danger is greater when there has been very little circulation in the old workings, and especially if there is a tendency to gob fires, since in such a case there would be a large amount of whitedamp given off. The presence of whitedamp is not as readily detected, when entering an abandoned working place, since the lamps continue to burn brightly in this gas. The effect of the gas is deadly, as it poisons the system, producing unconsciousness and death in a comparatively short time.

QUES. 4.—What is meant in the science of mine ventilation by the term "equivalent orifice"?

ANS.—In mine ventilation, the resistance offered by the mine to the passage of a ventilating current is often compared to the resistance offered to the flow of any fluid through an orifice in a thin plate. In each case, the velocity of the flow is proportional to the square root of the pressure or head which actuates the flow. The expression for the velocity of any fluid under a certain head

(h) is given by the equation $v = \sqrt{2gh}$, or since $v = \frac{Q}{a}$, we have

$Q = a \times \sqrt{2gh}$; and introducing the coefficient for the *vena contracta* in the flow through an orifice in a thin plate, we have, finally, $Q = .615 a \sqrt{2gh}$. In this equation, h is the head in feet actuating the flow. This can be reduced to inches (i) of water gauge, thus, $h = \frac{1,000}{1.2 \times 12} \times i$. Substituting this in the above

equation, and solving with respect to a , we have $a = \frac{.00038 \times Q}{\sqrt{i}}$.

This last equation gives the value of what is termed the "equivalent orifice" of a mine. It is the ratio between the quantity of air in circulation, and the square root of the water gauge producing the circulation. It is, in fact, the size of orifice in an imaginary thin plate which will pass this quantity of air under this pressure.

QUES. 5.—What are the uses of the following instruments in connection with coal mines: Anemometer, thermometer, barometer, and water gauge?

ANS.—The anemometer is used to determine the velocity of an air current. This instrument is shown in Fig. 1, and consists of a small vane having its blades inclined to the plane of revolution. The inclination of the blades is such that one revolution of the vane corresponds to a movement of the air of 1 foot, so that when the vane makes 60 revolutions in 1 minute the air is traveling at a velocity of 60 feet per minute. The revolutions of the vane are communicated to a recording dial upon the face of the instrument, by means of a series of gears. There is at the top of the instrument a small catch by which the hands of the dial are thrown out of or into gear, thus enabling the instrument to record the movement of air for an exact period of time, as noted by the watch.

The thermometer used in mining is the ordinary house thermometer. It is employed to ascertain the temperature of the air current, since any change in the temperature of a current will affect at once the volume or quantity of air in circulation. For this reason it is always important to note the temperature in connection with anemometer readings in careful investigations.

The barometer used in mining is usually the mercurial barometer. This is stationed upon the surface near the mouth of the mine. The aneroid barometer is sometimes employed when readings are to be taken in the mine. The barometer is used to indicate the atmospheric pressure. This is important in mining practice, since any change in atmospheric pressure affects the volume of the gases in the abandoned workings of the mine.

FIG. 1.

A fall of barometer or a decrease of atmospheric pressure, results shortly in the expansion of the gases in the abandoned workings, and causes them to flow out upon the airways and mingle with the air current. This will often produce dangerous conditions. On this account the barometer is carefully watched at large mines, especially where dangerous gases are being given off in the workings.

The water gauge and its use have been fully described in answer to Ques. 30, page 273, MINES AND MINERALS, January, 1900.

Ques. 6.—What are the different noxious gases found in the coal mines of Iowa? Give as fully as possible what is known of the properties, dangerous character, and method of detecting each of them.

Ans.—The gases occurring in the mines of Iowa are as follows: Carbonic-acid gas (CO_2), blackdamp; carbonic-oxide gas (CO), whitedamp; there is no marsh gas in the coal seams of this State. The properties, character, and methods of detecting these gases are fully described in answer to Ques. 3, page 85, MINES AND MINERALS, September, 1899.

Ques. 7.—How would you determine whether a cage and its attachments are safe, as operated in a mine?

Ans.—I would examine carefully the construction of the cage in regard to its workmanship and material. To determine any points of weakness, either in the cage itself or the rope or chains by which it was supported, I would subject it to a test by means of a heavily loaded car or other weights much in excess of what it would ordinarily be required to carry. I would also direct the engineer to start this load suddenly from the bottom, if I had any doubts as to the security of the holdings. In regard to the safety catches, I would have the rope so arranged that the cage could be cut loose, at some point in the shaft, when carrying a loaded car to satisfy myself of the working condition of the catches and their ability to prevent the cage from falling to the bottom of the shaft. I would also examine the guides from the top to the bottom of the shaft to see that they were secure and strong.

Ques. 8.—Describe in detail how you would test the scales at a mine, to determine their accuracy.

Ans.—I would first carefully balance the scale beam when the platform of the scales was empty. I would then place standard weights of 50 and 100 pounds upon the scale platform, testing the weight of each by the scale beam. I would then remove these weights and run an empty railroad car upon the scale platform, and, having balanced the weight of the car, I would again test the scales by the addition of the 50- and 100-pound standard weights. I would do the same again, using a loaded railroad car. In all of these tests I would require that the scale beam should break easily and correctly. These tests should be made at a time when there is no wind pressure operating upon the scale platform; since this may readily produce a difference of from 50 to 100 pounds.

Ques. 9.—In mining coal by the pillar-and-room method, what should be the rule for determining the size of pillars and relative size of rooms?

Ans.—The general conditions determining the size of room pillars are: (1) Depth of seam or thickness of cover, which determines the roof pressure. (2) Strength of roof and character of bottom; a hard roof or soft bottom requiring thicker pillars, while with a soft roof or hard bottom the pillars may be of less width. (3) The character of the coal, a soft frail coal requiring thicker pillars; while with a hard coal the width may be decreased. (4) The thickness of the seam increases the size or width of pillar. (5) The inclination of the seam also affects, to a greater or less extent, the thickness of the pillar, steep seams requiring thicker pillars than are necessary in seams of less inclination.

The size of openings, or width of rooms or chambers, depends largely upon the same conditions. (1) Thickness of cover or depth of seam, which determines the roof pressure, affects directly the width of the opening. The latter decreases as the depth increases. (2) A weak roof or soft floor, or frail coal each decreases the width of the opening, while a strong roof and floor, or hard coal may permit of wider openings.

No rule, other than a general rule, can be given for determining the relative width of pillar or size of opening. This must be determined alone by experience, in any given district.

Ques. 10.—If in extending the workings of a mine where the airways are kept of uniform size and condition, the water gauge shows an increased pressure, what, in your opinion, is its cause?

Ans.—It would be natural to expect an increase of pressure due to the increased length of airway, or an increase of rubbing surface. Also, in the extension of the mine workings, there would probably be more air required, and this would also call for an increase of pressure, unless the air current was split into two or more separate currents.

Ques. 11.—In case of an explosion in a mine, whereby, the

furnace, doors, and air stoppings were destroyed, what method would you adopt to restore circulation to admit of a prompt rescue within?

Ans.—The descent into the mine must be made by means of the downcast shaft. The doors, air stoppings, and other means of ventilation being destroyed, the shaft will be filled with the afterdamp of the explosion. This may be partially removed by means of water poured down the shaft. The work of restoring the brattices, stoppings, doors, etc. must be commenced at the bottom of the shaft. No advance can be made ahead of the air current. An attempt should be made to restore communication between the upcast and downcast shafts at once. What air current can be obtained should be carried forward by temporary brattices constructed of brattice cloth or boards nailed to rows of posts. As quickly as communication is established between the upcast and downcast shaft, the air current can be strengthened by hanging a fire basket in the upcast. The whole of this current should be directed forward along the main entry where exploration is already being made.

Ques. 12.—If the ventilation of a mine be insufficient where the power is fully utilized, what could you do to increase the amount of air in circulation?

Ans.—If the power is fully utilized in the present ventilation of the mine, the only means by which the quantity of air in circulation can be increased, without additional power, is to clear up the airways, enlarge the breakthroughs, and straighten the air courses as much as possible, thereby reducing the length the air must travel. All old curtains and brattices that are not required should be taken down, and the air be made to travel in as direct a course as possible. If this does not produce the desired result, recourse must be had to splitting the air; that is to say, causing it to travel in two separate currents, which has the same effect as increasing the area of the airway. The volume of air passing will be directly proportional to the number of splits made, provided these are of the same length and the power remains constant. The pressure will be reduced in the same ratio as the quantity is increased under these conditions.

Ques. 13.—How would you proceed to reduce the number of doors in a mine, and still maintain a good circulation of the air? What advantages would be gained by so doing?

Ans.—The number of doors required in the ventilation of a mine, is reduced by building overcasts at the points where there were formerly doors, and ventilating each pair of entries by a separate split of air, as shown in Fig. 2. The fresh air current, or the return air, will pass over these overcasts, or bridges, according as the haulage is accomplished upon the return air, or upon the intake air course. The advantages gained by reducing the number of doors required in the mine, is the reduction of expense for trappers necessary to attend the doors upon the haulways. Where trappers are not employed to open and shut the doors, there is a loss of time to the drivers on this account, and a consequent reduction of output or increase of expense per ton of output.

Ques. 14.—Describe the proper method of constructing doors and splitting air currents in a mine. How can the currents be regulated so as to furnish the proportion of air needed in different workings?

Ans.—The proper method of constructing a mine door of use for the purpose of deflecting an air current has been fully described in reply to Ques. 29, page 272, MINES AND MINERALS, January, 1900. The air current of a mine is split into two or more currents; whenever there are provided two or more separate ways by which the air can travel through the mine to reach the upcast. The air will divide itself between these several routes, or passages, according to the resistance of each. It will usually be necessary to construct an air bridge over the haulway either for the return or the intake current of that split, or of the main current. The construction of these bridges is fully described in answer to Ques. 29 referred to above.

The proportionate division of an air current, or any division other than the natural division is accomplished by means of regulators. The regulators in use are of two forms, known as the "box regulator" and the "regulator door." The former is shown in Fig. 3, and consists of a door or brattice built usually in the return airway, because this position will generally interfere less with the mine haulage. This form of regulator is provided with

FIG. 2.

a movable slide or shutter by which the opening may be increased or diminished at will, thus regulating the supply of air in the split which it controls. The other form of regulator shown in

FIG. 3.

Fig. 4, consists of a door *ab* at the mouth of two splits, so arranged that its cutting edge *a* is presented to the intake current. This door is provided with a set-lock, so that its position may be fixed to divide the air current into any desired proportions, between the two airways. This latter form of regulator consumes less

FIG. 4.

power than the former, since it does not increase the resistance of the split, as is the case when a regulator is placed at the return end of the split. In the use of the box regulator, the pressure of each split in which a regulator is placed is increased by the regulator till it equals the *natural pressure* in the free or open split; the pressure in all the splits then being equal. In the use of the regulator

door, the pressure for each split is simply the *natural pressure* of the split, and there is consequently much saving of power in the use of the latter form of regulator.

Ques. 15.—In a mine where the main air course and return are each of the same length, the roof has fallen badly in the former, while the air is foul in all the entries and working places, yet the fan is run to its full capacity. Name three ways by which the amount of air can be increased in such a mine without enlarging the fan.

Ans.—(1) The quantity of air in circulation may be increased by clearing up the falls upon the main air course, as explained in answer to Ques. 12 above. (2) The quantity of air in circulation may be increased by increasing the *speed* of the fan, but this will necessitate a large increase of power. (3) If this is a shallow mine, it may be cheaper to sink an air shaft at the head of the entries and cause the air to travel in two separate splits from the downcast to the upcast shaft. (4) It may be possible to build a furnace at the foot of the upcast shaft.

Removing a Body of Gas From Mine Workings.

The removal of a body of gas from a chamber or other working place where it has collected is often a difficult task, requiring close care and attention upon the part of the fire boss. The first duty of that official, before taking any steps toward the removal of a considerable body of gas, is to notify all the men working upon the return current who will be affected thereby. Where the accumulation of gas is large the men should be absolutely withdrawn from all working places inbye from where the gas is located, and the fire boss should assure himself that his orders in this respect have been fully carried out, both for the safety of the men in question as well as that of all those employed in the pit. The body of gas may move very quickly, and flow out upon the airway in large volume, rendering the air current highly explosive. On the other hand, the movement of the gas may be extremely sluggish, and despite every effort made to dislodge it, little progress may be made toward its removal. The fire boss cannot foresee these possibilities, however, with certainty, and his plain duty is always not only to notify the men affected, but to see that they are absolutely withdrawn.

Having increased the circulation in the affected district, as much as possible, the fire boss, with a few helpers, starts by

erecting a temporary brattice just beyond the mouth of the first room wherein such a body of gas has accumulated (see *a*, Fig. 1). This is done providing the crosscuts are open to permit the circulation to pass along the working face, from room to room, without returning to the airway. The effect of the brattice or curtain thus erected in the airway is to raise the ventilating pressure in the rooms. If these rooms are driven to the pitch, and the gas, as we have assumed, consists of a firedamp mixture, its tendency will be to rise to the face of the pitch and there remain. It will often require a considerable ventilating pressure to overcome this tendency of the gas to rise to the face in steep pitches. We have known of cases where a large body of gas, accumulated under similar conditions to these, refused, during a long period, to move at all; every effort made to start the circulation in these rooms proving unavailing. In one particular instance, as a last resort, but one thing remained to be done, and that was to start at the return end, where the current should discharge from the rooms, and erect a short brattice leading up into the chambers, as shown at *b*, Fig. 1. It will at once appear that it would not be possible to extend such a brattice far into the chamber, since the air would here be heavily charged with gas, causing the lamps to flame constantly, requiring the most careful watching, and rendering the work hazardous. The men, in this instance, were compelled to advance, set a post, nail the brattice cloth to it and retreat quickly, always keeping, however, upon the fresh-air side of the brattice. By degrees the brattice was carried up from the airway toward the face of the room, the air current traveling up one side of the brattice and returning upon the other side. In this manner, the gas was removed slowly but surely from the chambers, but the work required a most diligent watch being kept upon the lamps, and great caution being used, especially when nearing the head of the chamber. From time to time, the men went back upon the airway, to the intake end *a* of the rooms in question, and erecting there the brattice which had at first been unsuccessful, would try again to start the circulation through the rooms.

The conditions here presented form a very interesting study, as we reflect that it is just such conditions as these that frequently result in disastrous explosion. The men performing the work may often be willing to take greater risks than they have any moral right to do. In many cases, the removal of a body of gas is undertaken without the proper notification of the men affected; it being assumed that the accumulation of gas is small, and the matter is treated as one of little importance. The experience of many of our most trustworthy fire bosses is often such as would render them heroes, were they to be recorded; and yet they come so natural to these men, that they are often barely mentioned in their reports.

A fire boss should not be placed in charge of a larger territory than he can readily attend to. He should not be compelled to make undue haste in order to complete his rounds. He may, in such case, if not particularly conscientious, neglect certain places upon the assumption that they are clear of gas, and such neglect may be the price paid for many lives. Because any district is usually free of gas, in a mine where gas is known to exist in other districts, is no warrantable reason or excuse for the neglect to examine daily each and every place in such district. The examination must be thoroughly and carefully made. The fire boss should not be hurried in his movements, as it may often occur that he unconsciously passes under a considerable accumulation

of gas, and arrives at a point near the face from which he cannot beat a hasty retreat in safety, before becoming aware of the presence of a dangerous quantity of gas. This is altogether possible, under certain conditions, where the gas from a feeder at the face or in the roof has flowed along the roof for a considerable distance. The air in the room being quiet is comparatively free from any appreciable amount of gas as the fire boss enters, but the movement of his body as he advances along the airway causes eddies which mix the gas with the current. Not long since an occurrence of this nature took place in one of the mines of the anthracite district of Pennsylvania. The fire boss, a careful man, had proceeded a considerable distance toward the face of a chamber when he became aware of a considerable body of gas above him by the sudden flaming of his raised lamp. He lowered his lamp cautiously, but was unable to find a position

FIG. 1.

low enough where the flaming ceased, and realizing at once the urgency of his circumstances he smothered the lamp under his coat and started for the airway. This incident is only one of a thousand occurring daily in our mines, and illustrates very forcibly the fact that the movement of one's body, in passing through a narrow passage, will disturb a body of gas accumulated at the roof, and will cause it to mix in dangerous proportions with the air of the passageway. Under these circumstances, the fire boss often finds his retreat suddenly cut off when he is least aware that he has encountered danger. For this reason, it is all the more important that the work of the fire boss should not be hurried by the necessity of making his rounds within too small a limit of time. As before stated, it is such simple occurrences as these that afford us the many illustrations of unexplained disastrous explosions.

Quantity of Air Needed for Ventilation.

The quantity of air needed for the efficient ventilation of a coal mine is a subject concerning which there is a very great difference of opinion. The large number of mining accidents due to the lack of air supplied to the workings has made it necessary for legislators to enact very rigid laws in regard to this subject. These laws usually specify a minimum amount of air to be supplied to mine workings per minute. In respect to gaseous mines the law frequently goes further and specifies the number of men that shall be employed upon any one split of air, and also, frequently, the maximum velocity of the air, to be allowed at the face of the workings. It is right that the law should be thus specific in naming an actual amount of air to be maintained in ventilation. It is the duty of lawmakers to establish such regulations with respect to mine workings, as shall in their opinions make them safe under all conditions.

To any one acquainted with the very varying conditions of mines, however, there can be no specific and absolute amount of air, in cubic feet per minute, named which will be applicable in all cases, and very often the judgment of the mine inspector and of the mine operator has modified the amounts specified by law. There are some essential points to be observed which we must always bear in mind in the ventilation of the inner workings of a mine. First, the velocity of the current at the face should not be such as to render the workman uncomfortable. In a non-gaseous mine, the velocity of the air passing the face should not exceed 4 or 5 feet per second. There are often cases where a barely perceptible movement of air, at the face of the workings, is sufficient to maintain a pure and healthy atmosphere. Such cases are found where the development of the mine is small and the extent of abandoned workings is very limited. In gaseous mines, frequently, it is necessary to maintain a velocity which as nearly approaches the limit allowed by law as possible. This limit as specified in the Anthracite Mine Law of Pennsylvania, is $7\frac{1}{2}$ feet per second, or 450 feet per minute. It is necessary that this velocity be attained at the face of the workings as closely as may be, so as to enable the current to sweep away the gases which always accumulate in quantity at the face. If the velocity of the air falls much below this, some of the gas will still remain in the cavities of the workings, and will be a constant menace to the safety of the mine. With these facts before us, we see that the velocity of the air current sweeping the face of the workings is an essential point in all ventilation. Let us consider for a moment the conditions affecting the maintaining of this velocity.

(a) The thickness of the seams has very much to do in modifying the velocity of the current. At the face of the workings the air passages have a sectional area which is greater or less according to the thickness of the seam. Thick seams present a very large area for the passage of air, and a low velocity is the result; while thin seams present a small sectional area and the velocity is correspondingly high.

(b) The character of the roof and floor, and texture of the coal, inasmuch as they limit the width of the air passages, modify the velocity of the air current in the same manner. A poor roof, or soft bottom, or a frail coal, require narrow passageways, which present a small sectional area, and give a high velocity to the current; while strong roof, good bottom, and hard coal allow wider passageways, and a low velocity.

(c) The conditions, in a mine, which limit the number of splits that can be made in the current, also affect the velocity of the same; as the longer the split, in general, the larger the quantity of air required, and the higher its velocity.

Another essential feature of ventilation arises from the conditions relative to the amount of gas given off from the workings of a mine. Where much gas is given off, a larger current will be required in order to dilute those gases and render the same explosive. This evidently gives a very much larger volume of air than would be required for the use of men and animals, and for

the burning of the lamps, in the mines. The principal object, in this case, is the dilution of the gases. The amount necessary for this purpose can only be approximated as being proportional to the number of men employed or the extent of the working face.

Considering these several conditions which we have mentioned, and others relative to the temperature of the current and the ventilating pressure for the entire mine, as well as the amount of abandoned workings in the mine, which always gives rise to a large amount of carbonic-acid gas (blackdamp), we are brought face to face with the conclusion that the amount of air which should be supplied to any mine is really dependent upon conditions which can only be known to the men in charge of such workings. While the mine law must be carried out and enforced absolutely, it necessarily often imposes a condition which does not add to the comfort of the men. It, however, secures their safety and the general safety of mine workings. This is the purpose of the law. We have known instances where the miners at work upon a current of air that evidently fell below the requirements of the law, implored the inspector not to report the same, as they had a sufficient amount of air to render them healthy and comfortable, and they claimed further that any more air would "freeze them out." At another time, we knew a pit boss who had more education than veracity, and was evidently smarter than the inspector, who, knowing that the air was short in the main intake, followed the inspector into the airway; and, pretending interest in watching the instrument with which the air was being measured, interposed his body in the area of the airway, thereby giving a greater velocity to the air current at that point and securing a higher record for his mine than would otherwise have been obtained. The inspector did not notice the trick. We have known other inspectors who have been persuaded to measure the air upon the return current of the mine, and record the same as the air passing into the mine; perhaps never realizing that this return current, having a higher temperature and laden with the gases of the mine, presented a relatively larger volume than should have been recorded as entering the mine.

Rope Transmission in Mine Haulage.

There are a few general rules that must always be complied with in the installation of any rope haulage. Some of these rules are of particular importance in the application of rope haulage to mining.

Straight Haulways.—It is quite generally understood that any rope transmission should be planned in as straight and direct a manner as possible. The haulage roads in mines are often tortuous, and it would be a matter of considerable expense to make these roads straight. On the other hand, there is a great saving in expense, for maintenance of tracks and ropes, when the haulways can be made fairly straight. On this account, when rope haulage is installed upon a road that is at all tortuous, and this road is to be made the future main haulage road of the mine, it will often be a good investment to expend some money in the straightening of this road before installing the system.

Grades of Haulways.—If the road has numerous hills and swamps, giving short, varying grades, it will generally be practicable and advisable to cut the hills and fill the swamps, so as to render the grade of the new road fairly uniform. This is always done in the larger mines in laying out a main haulage road. There are two benefits arising from the establishment of a grade that is fairly uniform. (1) The load upon the winding engine is made more uniform. (2) There is a very considerable reduction in the wear and tear upon the rope. When a haulage rope crosses a hill, it bears heavily upon the carrying rollers placed in the middle of the track. This often causes a rapid wear of the wooden rollers, necessitating their being replaced frequently, and there is always an increased wear upon the rope. This trouble, however, upon the hills, is not as great as what occurs where the rope crosses a sag in the road, or what is termed in mining, a "swamp." At this point, the rope is lifted clear of the carrying rollers, and jumps violently up and down by reason of the varying tension caused by the loaded trip. At such points of a haulage road, we have seen the main rope of the loaded trip vibrating from top to bottom, and from side to side of the entry, rendering the passageway unsafe for any one whose duties might call him hither. The consequent wear and tear upon the rope under such conditions is enormous, and no one would hesitate to make a considerable outlay in order to avoid the trouble. There should be no sudden change of grade at the foot of an incline. The change of grade should be so moderate that the weight of the rope will prevent its being lifted too high off the rollers. It is generally possible to obtain this result by using a little judgment and foresight in the arrangement of the grades.

Rollers and Carrying Sheaves.—The location of the rollers and carrying sheaves for any haulage rope should be such that the rope will bear continuously and regularly upon the rollers as far

as practicable. There are various forms of rollers and carrying sheaves in use. When the rope lies in the center of the track it is commonly carried by a small wooden roller (Fig. 1) of say 5 inches in diameter, and from 12 to 18 inches in length. These are usually turned from oak or other hard wood, and fitted with a short iron rod inserted into the center of each end as a journal or bearing. When the rope is carried along the side of the haulway, cast-iron sheaves (Fig. 2) are often employed, having a diameter varying from 10 to 16 inches, the faces of the sheave being often chilled to increase their wear. These rollers should always be set so that their alignment is true. Wherever there is a deflection of the rope, the carrying sheave should be inclined so as to lie exactly in the plane of the deflected rope. This rule is very important. Track rollers are usually spaced from 5 to 8 yards apart. Carrying sheaves along the sides of the roadway are placed at convenient points, varying from 10 to 20 yards apart. At times, the rope is carried over the haulway, ordinary track rollers being hung from the collars or framing sets. Rollers and carrying sheaves are usually mounted in wooden bearings made by boring a hole in a piece of oak of suitable thickness. These bearings are kept well oiled.

Guide Sheaves.—Guide sheaves are necessary wherever the rope is carried around a curve, or changes its direction. Numerous forms of guide sheaves are employed, but these are usually arranged according to two general systems. Whenever a haulage rope is deflected through a certain angle it must be (1) carried around a grooved sheave of sufficient diameter as not to injure the rope by bending; or (2) numerous small sheaves or rollers must be employed, spaced at regular distances apart, and so arranged that their centers shall lie in the arc of a circle. The first arrangement is usually employed where the tail rope is deflected through a considerable angle in the mine, as, for example, where the rope passes from a main heading to a crossheading. The sheave used in this case is a large cast-iron grooved sheave similar to those employed at the top of headframes for hoisting, but is placed in a horizontal position. The groove is usually lined with oak blocks the same as in hoisting sheaves. The second arrangement is employed where the main rope is carried around a curve in the haulage road. The main rope must of necessity conform to the track; and when the direction of the roadway changes, guide sheaves are necessary in order to deflect the rope. The simplest form of guide sheave employed is that shown in Fig. 3. This form is used where only a slight change occurs in the direction of the track. This is the same form of roller as shown in Fig. 1, made shorter and set upright. An iron strap is usually employed, as shown in the figure, to supply the upper bearing.

The form of roller shown in Fig. 4 is often used around a curve, and is placed at the side of the track, outside of the inner rail of the curve. These rollers are often slightly inclined from the vertical. They are made of cast iron, chilled or case hardened. The flange is set upward, and is for the purpose of preventing the rope from traveling higher upon the roller. These rollers are usually spaced from 2 to 3 feet apart around the curve. Another form of guide sheave used in conveying the rope around the curve in the track, is that shown in Fig. 5. This form consists of a carrying sheave, the same as shown in Fig. 2, but placed in a horizontal position.

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

FIG. 5.

of the bending stress. Thus, to obtain the bending stress for a rope of a given diameter, passing over any given sheave, we may multiply the ratio of the diameter of the rope to the diameter of sheave by the ratio given above for the size of rope used, which will give the ratio of the diameter of the wire to the diameter of

the sheave $\left(\frac{d}{D}\right)$; and substitute this value in the expression for

the bending stress, $E \frac{d}{D}$. For example, suppose a 1-inch rope passes over a sheave 8 feet in diameter, the rope being a 7-wire rope, the bending stress in this case will be

$$26,000,000 \times \frac{1}{8} \times \frac{1}{12} \times \frac{1}{7} = 30,000 \text{ lb. per sq. in.}$$

This rope having six strands contains $6 \times 7 = 42$ wires, whose diameters are each, approximately, $\frac{1}{4}$ inch. The area of cross-section for these wires will therefore be $42 \times .7854 \times \left(\frac{1}{4}\right)^2 = .4167$ square inch. Multiplying this area of cross-section by the stress per square inch (30,000 lb.), we obtain for the bending stress $.4167 \times 30,000 =$ say 12,500 pounds, or 6.25 tons. This means that the rope, in its passage over the sheave, is subjected to a bending stress in its outer wires, equivalent to an additional load of 6.25 tons

tion. These sheaves are arranged at equal distances outside of the inner rail, and at regular intervals apart, all the way around the inside of the curve. At each roller or sheave in Figs. 4 and 5, and at suitable intervals between them, oak blocks are arranged for the purpose of allowing the rope to slide into position in the groove of the carrying sheaves, and to prevent its catching in the rail as the trip goes around the curve.

Bending Stress in Ropes.—It is a well known fact that, when a wire rope is bent through a certain angle, the stress in the outer fibers is greater than that of the inner fibers of the rope. When the angle of bending is too great at any one point, the rope is permanently injured. The bending stress in a rope, or the stress due to the bending of a rope around a given sheave, is calculated for the outside fiber of the rope, or for a single wire of the rope lying outermost in the curve, since it is this wire that is subjected to the greatest bending stress. The bending stress in pounds per square inch to which the outer wire of a rope is thus subjected is

given by the expression $E \frac{d}{D}$, in which E = modulus of elasticity

(for steel, $E = 26,000,000$); d = diameter of a single wire of the rope (inches); D = diameter of sheave (inches). The bending stress obtained by this formula is the stress in pounds, per square inch, exerted upon the outermost wire of the rope. Since, however, previous to bending over the sheave, each wire of the rope

carries its proportion of the actual load, the bending stress should be calculated for all the wires of the rope, or the entire sectional area of wire in the rope, and this load due to bending, or the bending stress added to the actual load carried by the rope. This is the true load upon the rope, because the strength of a rope is determined by the strength of its ultimate fiber.

The fact that the ratio of the diameter of the wire to the diameter of the rope is for 7-wire ropes $\frac{1}{7}$, for 12-wire ropes $\frac{1}{12}$, and for 19-wire ropes $\frac{1}{19}$, approximately, may simplify the calculation

FIG. 6.

FIG. 7.

upon the rope. The proper working load allowed for this rope, as taken from catalogue of makers, is 8.4 tons. Subtracting the bending stress calculated above, we have $8.4 - 6.25 = 2.15$ tons, actual net load that should be allowed upon the rope.

TABLE I.

SHOWING DIAMETERS OF MINIMUM SHEAVES FOR STEEL AND IRON ROPES OF DIFFERENT SIZES AND KINDS.

Diameter of Rope (Inches).	Steel Rope, 6 Strands.			Iron Rope, 6 Strands.		
	7-Wire (Inches).	12-Wire (Inches).	19-Wire (Inches).	7-Wire (Inches).	12-Wire (Inches).	19-Wire (Inches).
1/16	19	14	12	40	30	24
1/8	24	18	14	50	38	30
3/16	29	22	17	60	45	36
1/4	34	25	20	70	53	42
5/16	38	29	23	80	60	48
3/8	43	32	26	90	68	54
7/16	48	36	29	100	75	60
1/2	53	40	32	110	83	66
5/8	58	43	35	120	90	72
3/4	67	50	40	140	105	84
7/8	77	57	46	160	120	96
1	87	64	52	180	135	108
1 1/8	98	72	58	200	150	120
1 1/4	109	80	64	225	170	135
1 1/2	120	88	71	250	190	150

Since the breaking strain of this rope is 42 tons, if the rope were to be loaded with a net load equal to its full working capacity (8.4 tons), the total load upon the rope, including bending stress at the sheave, would be $8.4 + 6.25 = 14.65$ tons; and there would result only a factor of safety of $\frac{42}{14.65} = 3$, nearly. These conditions, however, or the loads just calculated, are the ultimate loads

Table I showing the minimum diameter of sheave in inches, required for steel and iron ropes of various diameters, as taken from the Trenton Iron Co.'s "Wire Rope Transportation." This table, it will be noticed, differs from previous tables, which were revised as the quality of the ropes were improved. The table has been extended beyond that given in the catalogue, to include ropes of $1\frac{1}{8}$, $1\frac{1}{4}$, $1\frac{1}{2}$, and $1\frac{3}{4}$ inches in diameter.

Table No. I has reference only to the minimum sizes of sheaves permissible, where the rope is so loaded and deflected through such an angle that its curvature is the same as the curvature of the sheave. Where a rope transmitting power passes over a sheave and is deflected through a given angle, the rope does not necessarily conform to the curvature of the sheave. To make this plain and to understand more clearly what follows, we will refer to Fig. 8, which represents a wire rope deflected through a small angle α , by a cord C tied to it at A. We observe at once that the rope, on account of its rigidity, does not bend in a sharp angle at the point where the string is tied, but assumes a gradual curvature. The radius of this curvature is dependent upon several factors. (1) The tension upon the rope or the pull upon each end. (2) The angle of deflection or angle of bending. (3) The rigidity of the rope. The first two factors mentioned are easily assumed, for any given case; the third factor is more or less indeterminate, since an old rope, or one in use for a considerable period of time, has not the rigidity possessed by a new rope. The only method of comparison that can be made must be based, however, upon new ropes, since old ropes may have any varying amount of rigidity. We give below a table slightly modified from the table found in The Trenton Iron Co.'s "Wire Rope Transportation," previously referred to, and which shows the radius of curvature in inches, for a new rope, for different angles of deflection varying from 5° to 90° and different diameters of rope.

The radii of curvature given in this table are expressed in inches, and are for a tension of 1 pound upon the rope. These

TABLE II.

SHOWING THE RADIUS OF CURVATURE IN INCHES OF NEW STEEL 7-WIRE AND 19-WIRE ROPES OF DIFFERENT DIAMETERS, HAVING A LOAD OF ONE POUND UPON THE ROPE AND HAVING AN ANGLE OF DEFLECTION OF THE ROPE VARYING FROM 5° TO 90° .

5/16	448,907	224,667	150,016	112,763	90,469	75,655	65,117	57,251	51,168	46,329	42,406	39,162	34,138	30,463	27,892
3/8	678,328	339,982	225,012	169,135	135,696	113,477	97,670	85,872	76,747	69,489	63,606	58,740	51,205	45,692	41,585

to which the rope is subjected. Attention is drawn here to the load due to bending, as being included in the "Proper Working Load" for a rope, and allowance must always be made for this when determining the size of rope required. In practice, the factor of safety varies from 3 to 10, according to the importance of the rope and the magnitude of the accident that would result from its breaking. The factor of safety for inclines should not be less than 6, while a factor of safety of 3 would be sufficient often for flat roads.

Size of Sheave.—Since the bending stress in the rope increases as the diameter of the sheave decreases, there is a practical limit to the size of sheave that should be employed with different sizes of ropes. It is common practice, in the use of steel ropes for haulage purposes, to employ sheaves whose diameter is not less than 80 times the diameter of the rope. This rule refers only to haulage ropes made of six strands with seven wires in each strand. In the use of steel ropes of 12 wires, the diameter of the sheave should not be less than 60 times the diameter of the rope. Steel ropes of 19 wires (hoisting ropes) require sheaves whose diameter is not less than 50 times the diameter of the rope. In the use of iron ropes, these ratios are doubled; in other words, an iron wire rope of the same number of wires requires a sheave having double the diameter of that employed for a steel rope. We give here

radii must in each case be divided by the actual tension or load upon the rope in question, since the radius of curvature varies inversely as the tension upon the rope, for the same angle of bending.

This table has a very interesting application in the practice of wire-rope transmission. When the angle of deflection of a rope is small, or when the angle is considerable and the rope is not heavily loaded, a smaller sheave than that specified as a minimum sheave for this rope may be employed without damage to the rope; for the reason that owing to the rigidity of the rope the radius of curvature of the rope is not the same as the radius of the sheave. For example, a new 1-inch 7-wire haulage rope loaded to only one-half ton (1,000 lb.) would, according to the data furnished us in Table II assume a curvature whose radius is $48,949 =$ say 49 inches when deflected through an angle of 90° .

$1,000$ This corresponds to a diameter of $49 \times 2 = 98$ inches. Under this load and for this angle of deflection, a new rope would not conform to the curvature of a sheave whose diameter was less than 98 inches, and therefore a smaller sheave than this should not be used for this load.

The most interesting application, however, lies in the problem of carrying a haulage rope around a curve in the roadway. In

this case, small sheaves must be employed, set side by side at given distances around the curve (see Fig. 7). If it were true that, however small the angle of contact upon the sheave, the rope partook of the curvature of the sheave and was thereby damaged when passing over a small sheave, it would not be possible to carry a haulage rope around the curve in a track without damage, except at great inconvenience growing out of the employment of sheaves of very large diameter. Since, however, a rope assumes its own curvature, depending upon the load it carries and the angle of deflection, it is possible to set small sheaves at such distance apart around the curve in the track as to reduce the angle of bending (a) at each sheave so that the curvature of the rope will be less than that of the minimum amount given in Table I. For any given curvature of track the angle of deflection at each sheave is smaller as the sheaves are closer together.

Calculation of Distance Apart of Guide Sheaves Around Curves. There are two previous steps in the calculation of this problem. (a) To determine the radius of curvature for the rope in question, for a load of 1 pound upon the rope. (b) To determine the angle of deflection at which this rope will assume this radius, under a load of 1 pound.

(a) To calculate the radius of curvature permissible for a load of 1 pound, we use the formula

$$R = .7854 \frac{E n d^3}{2}, \quad (1)$$

in which R = radius of curvature of the rope (inches);

E = modulus of elasticity (steel, 26,000,000 to 32,000,000, say 28,000,000; iron, 22,000,000);

n = number of wires in the rope;

d = diameter of single wire (inches).

When the rope is made of wires of different diameters, the entire sectional area of wire in the rope, $n(.7854 d^2) = A$, is estimated separately, and the formula then becomes

$$R = \frac{E A d}{2}, \quad (2)$$

in which A = entire sectional area of wire in the rope (sq. in.);
 d = diameter of outer wire (inches).

(b) Having calculated the radius of curvature, observe from Table II the angle of deflection that corresponds to the radius

FIG. 1.

next higher, and assume this angle as the angle of bending at each sheave supporting the rope around the curve.

Having determined the angle of bending at each sheave, we have the angle of deflection for the track curve between two consecutive sheaves. We then subtract from the radius of curvature of track center the distance from the center of the track to the line of the sheaves to obtain the radius R_1 (Fig. 7). Then applying geometry, we have

$$s = 2 R_1 \sin \frac{1}{2} a, \quad (3)$$

in which, s = distance between the centers of guide sheaves (feet);

R = radius of center line of sheaves (feet);

a = angle of bending or deflection of rope at each sheave.

EXAMPLE.—A 1-inch 7-wire steel haulage rope is to be carried around a curve in a track. The radius of the track center curve is 50 feet, and the guide sheaves are set with their centers 3 feet from the track center. What is the proper distance between the centers of the guide sheaves?

SOLUTION.—Substituting values in formula (1), remembering that, as there are six strands with seven wires in each strand, $n = 6 \times 7 = 42$ wires, and since the ratio of the diameter of the wire to the diameter of the rope is, approximately, $\frac{1}{4}$ for 7-wire ropes, we have for the permissible radius of curvature of this rope, for a load of 1 pound,

$$R = \frac{.7854 \times 28,000,000 \times 42 \times \frac{1}{64}}{2 \times 9^2} = 633,500 \text{ in.}$$

Referring now to Table II, we observe that the next higher radius for a 1-inch 7-wire rope is 793,500, and this corresponds to a deflection angle of 5° . We therefore will assume this angle as the angle of bending of the rope at each sheave, or the angle (a) between the radii drawn to two consecutive sheaves. Finally, substituting in formula (3), we have

$$s = 2(50 - 3) \sin 2^\circ 30' = 94 \times .04362 = 4.10 \text{ ft.}$$

Haulage.

(Continued from August.)

The Endless-Rope System of Haulage.—As has been previously mentioned, this system of haulage is better adapted to seams which present a fairly uniform grade throughout the entire length of the roadway. The reason for this is found in the fact that where the grades are short and variable, a varying load will be thrust upon the winding engine, if the moving cars are distributed along the entire length of the roadway. This is more particularly the case when the cars forming the several individual trips are not spaced at regular intervals along the rope, which is a common occurrence in mine haulage. The numerous occurring delays both in the delivery of cars by the inside drivers at the parting where the trips are made up, as well as the delays incident to loading, at the tippie render it practically impossible that the several trips shall be regularly spaced. There is, in fact, no regularity in regard to the distance between the trips for empty or loaded cars. As a result, many of the loaded trips may be on an ascending grade at the same time; or they may all likewise reach a descending grade at once. This will render the load upon the engine very irregular and often very hard to control, especially if the engine is worked already to a point approaching its capacity.

The most of the details in relation to the conducting of a haulage rope into and through the mine passages, have been already described in previous articles. In this article we will refer to and describe only those details that have particular reference to the endless-rope system of haulage.

The Winding Drum.—The winding drum in the endless-rope system is very different from that employed in a tail-rope system. Here, the rope being an endless rope, is made to pass two or three times around the drum and then winds off. Only such a number of coils are made around the drum as will provide the friction necessary to prevent slipping of the rope. The number of coils required for this purpose will depend upon the pull of the rope, which varies according to the length of the haulage, the grade of the road, the load being hauled, etc. It is not necessary for this purpose that the drum should be a long drum, as is required in the tail-rope system. A difficulty arises, however, in regard to the fleeting of the rope along the face of the drum where a single drum or sheave is used.

FIG. 2.

This difficulty has been referred to, and the best method of overcoming it described, in an article, page 524, MINES AND MINERALS, June, 1900. Driving sheaves having a single groove are sometimes used in place of drums, in the endless-rope system where the haulage is light; but a large amount of wear upon the rope always takes place in their use, and for this reason they are not to be recommended. In their place have been substituted two drums, arranged tandem to each other, each drum having three or four grooves upon its face, according to the number of coils the rope is required to make about the drum. In the use of these tandem drums, the wear upon the rope is reduced to a minimum, the rope making a half coil upon each drum and passing to a different groove for each coil that it makes.

Balance Car.—One of the difficulties to be overcome in the operation of the endless-rope system that is not met in the other systems, arises from the fact that the rope, being an endless rope, requires some appliance for taking up the elongation of the rope due either to change of temperature or to the stretch of a long rope. The simplest appliance introduced for this purpose is that of the balance car. This is represented in Fig. 1. Its location is usually outside of the mine at some convenient point in the rear of the engine. The rope winding off from the drum passes directly around the large sheave C mounted upon the balance car A , and from thence is conducted into the mine. The rope on its way to and from the balance car passes over the large deflecting sheave B . The position of the balance car is thus seen to be at the outer end of the empty rope, or the rope which draws the empty cars back into the mines. The haulage rope is one continuous rope

running in and running out of the mine; but it is proper to speak of the ingoing and outgoing sections as the empty and loaded ropes, respectively. As shown in the illustration, the balance car *A* rests upon a short plane of a fixed inclination. The weight of the car should be such as is found necessary to keep the empty rope taut. As the rope stretches or as its length varies, due to changes of temperature, the balance car falls or rises upon the inclined track. If there is a tendency of the rope to slip upon the winding drum of the engine, this may be overcome by increasing the weight in the balance car.

Roadway.—In this system of haulage there is of necessity a double track, one for the loads and one for the empty cars. At times these tracks are laid in the same entry, but this requires a good roof and floor throughout the entire length of the road. These conditions are seldom found in mining, on which account the loaded and empty tracks usually occupy different passageways.

In some few instances single tracks are used in the operation of the endless-rope system, passing tracks being arranged at intervals along the road. In such cases it is necessary to have trip riders to ensure that each trip takes its proper siding and waits at that point until the trip passes it going in the opposite direction. When this arrangement is adopted the trips usually consist of several cars. If there were a certainty in regard to the spacing of the cars at regular intervals along the rope, the trip riders could be dispensed with by using automatic switches at each end of the parting or passing tracks; but this system would require numerous track walkers whose duty it would be to see that everything was moving smoothly, although it is often claimed by careful engineers that they can at once detect when anything is wrong below by the action of the rope and the engine. The automatic switch is a switch having a spring latch that is kept set for the empty track upon the outbye end, and for the loaded track upon the inbye end of the parting. This switch is shown in Fig. 2. The spring of the latch is furnished by a simple spring-pole spiked to the ties outside of the rail. There is nothing in the single track system, however, that recommends itself for the operation of this type of haulage.

Grips.—There are several forms of these in use for attaching

the car to the rope. Two features present themselves for consideration in relation to the cable grip, in endless-rope haulage. These are: (a) The constant motion of the rope. (b) The inertia of the load. The chief difficulty arises in providing a grip that will impart the motion of the rope to the standing cars without causing undue abrasion of the rope. The rope running at a uniform velocity and the cars being at rest, much injury will be caused to the rope by a grip that is not designed to prevent the undue wear of the rope. The simplest form of grip in use is the common type known as "grip tongs," shown in Fig. 3. This style of grip is very hard upon the rope; especially if the jaws of the grip are not lined, as they should be, with soft metal. The metal lining is readily replaced when worn, and saves the rope from wear to a large extent. When several cars coupled together are run in a single trip, the form of the grip must be such as to give a greater pressure, as the common grip tongs will slip, from time to time, and do much damage to the rope. Such a form of grip is shown in Fig. 4. It consists of two strong steel plates *m* and *n*, bolted together, one of these supporting the lower jaw *p* of the grip. The upper jaw is provided with a shank that slides up and down between the plates. This shank is operated by the eccentric motion of the lever *r*. When this lever is raised to an upright position, the upper jaw of the grip is lifted; when the lever is thrown down, the cable is pressed very strongly between the jaws. The jaws of the grip are lined with soft metal to prevent the undue wear of the rope.

Grips are often attached to the mine car directly, such forms being made detachable. When many cars are run in a trip, it is customary to have what is known as the grip car, which is a simple platform truck carrying a substantial grip beneath it. The trip rider who operates the grip rides upon this car. The grip, which is usually of the form shown in Fig. 4, is provided with a

FIG. 3.

FIG. 4.

sidelong motion that enables it to pass the guide sheaves, located at different points along the track.

District Haulage.—In the development of a mine, it often becomes necessary to extend the haulage rope, in more than one direction; as for example, when several pairs of cross-entries cover too large a territory to admit of mule haulage. There are two methods possible in such a case. The first of these methods is to carry the main rope into each cross-entry and passing it over a tail sheave return it to the main entry again, where it pursues its original course. The same rope runs in each pair of cross-entries and performs the entire haulage of the mine. This method has numerous disadvantages. It entails the constant running of the ropes, in all the districts of the mine, which means a considerable loss of power. A break in any one district affects the haulage system of the entire mine; and haulage must cease until such break is repaired. The better plan is to perform the haulage in each district by a separate rope. In this method, a fleet wheel is located in the main road at the mouth of each district, and the main rope makes one or two complete turns around this wheel, and then continues on its course along the main road. The fleet wheel at the mouth of each district furnishes the motive power for running the rope in that district. It is connected with the driving sheave for the district, by means of two beveled gears. In Fig. 5, the fleet wheel is shown at *d*, the beveled gears at *g* and *h*, and the driving sheave for the district at *m*. The driving sheave may be thrown in or out of gear, as desired, by the levers *o* and *q*. This permits the running of the rope in any district, as it is required; and when not in use, the district rope may be thrown out of gear. It will be observed that both the fleet wheel and the driving sheave, for any district are simple grooved sheaves, which gives rise to a considerable wearing of the haulage rope, as was explained in a previous paragraph, in relation to winding sheaves of this form being employed instead of tandem drums at the engine.

CALCULATION OF POWER REQUIRED FOR ENDLESS-ROPE HAULAGE.

(a) **Flat Seams.**—The conditions here vary from the conditions in tail-rope haulage. (1) Whether the opening is a shaft or slope

opening, the weight of the descending rope always balances the weight of the ascending rope. (2) Whatever the variations of grade along the line of haulage in the endless-rope system, these may be neglected, as the load upon the rope is assumed to be distributed along its entire length. In the tail-rope system of haulage, the entire load

must at some time be concentrated upon the steepest grade in the road. It is true that circumstances may occur when the most of the loads, in the endless-rope system, will be either ascending or descending a grade at once. For this reason it is not advisable to adopt this system, when the grades are variable, as previously stated; but if these conditions exist, in the operation of this system, ample allowance must be made when calculating the power of the engine, to provide against such untoward conditions.

For endless-rope haulage, in flat seams, ignoring variations in grade, the load upon the rope at the engine, is equal to the friction pull of the entire system. To determine this, we must know the entire output, speed of winding, length of haulage road, and the capacity and weight of the mine cars; and must find therefrom the size of rope required, since the friction of the rope must be added to the friction of the cars, in calculating the load upon the engine.

Let

- O = output (lb. per min.);
- v = speed of winding (ft. per min.);
- l = length of haulage road (ft.);
- c = capacity of mine car (lb.);
- w_1 = weight of mine car (lb.);
- w = weight of rope per lineal foot (lb.);
- T = load on the rope (lb.).

$$\text{Then, } \frac{1}{v} O = \text{weight of coal in transit; } \frac{2}{v} \frac{O}{c} \times w_1 = \text{weight of}$$

moving cars, loaded and empty; $2lw$ = weight of entire rope; $\frac{lO}{v} \left(1 + \frac{2w_1}{c}\right) + 2wl$ = entire moving load.

Calling the coefficient of rolling friction $\frac{1}{c}$ of the weight of the moving load, we have for the load on the rope, which in this case is the friction pull only,

$$T = \frac{1}{40} \left[\frac{lO}{v} \left(1 + \frac{2w_1}{c}\right) + 2wl \right].$$

Multiplying the load or pull on the rope by the velocity of the rope or speed of winding v and dividing by 33,000, we have finally for the horsepower required for this haulage,

$$\text{H. P.} = \frac{l}{40 \times 33,000} \left[O \left(1 + \frac{2w_1}{c}\right) + 2wv \right].$$

EXAMPLE.—Let it be required to find the horsepower necessary for an output of 1,000 tons per day (10 hours) where the endless-rope system is employed; the length of the haulage being 5,000 feet from the return sheave to the bottom of the shaft, the seam being generally flat and having a thickness of 5 feet.

SOLUTION.—We will assume in this case that the height of the haulage road is $5\frac{1}{2}$ feet, in the clear above the rail, and that the mine cars have a capacity of 2,000 pounds of coal, and weigh 1,200 pounds each. We will assume a speed of winding of, say 8 miles per hour, or $\frac{8 \times 5,280}{60} = 704$ feet per minute. For the output in

this case we have, $O = \frac{1,000 \times 2,000}{10 \times 60} = 3,333$ lb. per min.

Size of Rope.—Substituting the given values, in the above formula to find the load upon the rope, assuming for the purpose of calculation a one-inch rope, whence $w = 1.58$, we have

$$T = \frac{1}{40} \left[\frac{5,000 \times 3,333}{704} \left(1 + \frac{2 \times 1,200}{2,000}\right) + 2 \times 1.58 \times 5,000 \right] = 1,697, \text{ say } 1,700 \text{ lb.}$$

We observe we could use a much smaller rope, in this case, than a one-inch rope, if we considered the load only; but in haulage the wear upon the rope is often a more important factor than the load, in determining the size of rope to be used. For this haulage we would prefer not to use a smaller rope than the one assumed above.

Horsepower of Engine.—Substituting the given values, in the formula given above for determining the horsepower of this haulage, we have,

$$\text{H. P.} = \frac{5,000}{40 \times 33,000} \left[3,333 \left(1 + \frac{2 \times 1,200}{2,000}\right) + 2 \times 1.58 \times 704 \right] = 36.2 \text{ h. p.}$$

Then, assuming the efficiency of the engine as, say 60%, we have $\frac{36.2}{.60} = 60$ total horsepower of engine.

Size of Drum.—Using a one-inch rope, we will employ a drum having a diameter of, say 80 inches, since the minimum diameter of sheave for this rope is about 77 inches. A winding speed of 704 feet per minute will require $\frac{704 \times 12}{3.1416 \times 80} = 33.62$ revolutions of drum per minute.

Size of Engine.—For this horsepower (60 h. p.) we may assume a speed of, say $n = 350$ strokes per minute. We will adopt a duplex engine, running upon second motion, under a mean effective cylinder pressure of 60 pounds per square inch. Assuming the ratio of the length of stroke to the diameter of the cylinder, $r = \frac{l}{d} = 1.5$, and using the formula given upon page 569,

MINES AND MINERALS, July, 1900, we have for the diameter of the cylinder

$$d = \sqrt[3]{\frac{60 \times 33,000 \times 12}{.7854 \times 60 \times 1.5 \times 350}} = 9.866 \text{ in., say } 10 \text{ in.}$$

Length of stroke = $9.866 \times 1.5 = 14.8$ in., say 15 in.

The engine for this haulage is, therefore, a duplex second motion engine, 10" × 15".

Ratio of Gearing.—The ratio of gearing, $r_1 = \frac{\text{diam. of gear wheel}}{\text{diam. of pinion}}$,

when we have given the diameter of the drum D , in inches; speed of winding v , in feet per minute; and the strokes per minute of the engine n , is obtained as follows:

$$r_1 = \frac{\pi D n}{2 \times 12 \times v} = \frac{3.1416 \times 80 \times 350}{2 \times 12 \times 704} = 5.2.$$

That is to say, for every 10 teeth in the pinion upon the crank shaft, there must be 52 teeth in the gear wheel upon the drum.

(b) **Inclined Seams.**—Under this head, is included any system of endless-rope haulage where the load is lifted through a given

vertical height. This may apply to haulage in a flat seam which is reached by a rock slope; or to haulage in seams having a general inclination or dip from the foot of a shaft, inbye. The calculation of power, in this case, is the same as that in the previous case (a), except that the work Oh must be added, or the work due to lifting the coal ($O =$ output per minute) through a given vertical height h . The weight of the cars and rope is always assumed to be balanced; but as previously mentioned in the endless-rope system, when the grade of the haulage road is variable, ample allowance must be made to provide for emergencies which arise when there are delays.

The grade of the roadway, where this is considerable, will increase the tension or pull upon the rope, by the gravity pull due to the weight of the rope and the loaded cars, or as many of them as can occupy the grade at one time. The load upon the engine, however, will only be increased by the gravity pull due to the unbalanced load or output on the grade.

For purposes of calculation, it is simpler to estimate the additional work to be performed per minute due to the grade of the incline, for the elevation h , by means of the expression Oh . The total work per minute u will then be expressed as follows:

$$u = \frac{l}{40} \left[O \left(1 + \frac{2w_1}{c}\right) + 2wv \right] + Oh.$$

Assuming the same conditions as given in the previous example (a), except that in the entire length of the haulage there is a general elevation or rise of, say 100 feet, we may apply this formula to determine the effective work per minute performed in such haulage. It is to be observed that the elevation or rise h may occur from the general dip of the haulage road from the shaft bottom, inbye; or it may all occur in the slope, at the end of the haulage road, as when a flat seam is opened by a rock slope; or it may occur at any other point in the haulage road. The method of calculation will be the same in each case.

The change of grade from a level roadway to a rise, must never be so abrupt that the weight of the rope and the loaded cars, spaced at regular intervals, will not cause the rope to lie upon the rollers. The rope may lift from the rollers slightly between the cars or trips; but there should be no tendency to lift the empty cars from the track.

Assuming the above conditions we have for the effective work of the engine per minute, in this case,

$$u = \frac{5,000}{40} \left[3,333 \left(1 + \frac{2 \times 1,200}{2,000}\right) + 2 \times 1.58 \times 704 \right] + 3,333 \times 100 = 1,528,050 \text{ foot-pounds per minute} = 46.3 \text{ h. p.}$$

If we assume the efficiency of the engine as 60%, we have $\frac{46.3}{.60} = 77$ total horsepower of engine.

For the size of engine, in this case, assuming as before a duplex, second-motion engine, with steam pressure at 60 pounds per square inch, we have

$$d = \sqrt[3]{\frac{77 \times 33,000 \times 12}{.7854 \times 60 \times 1.5 \times 350}} = 10.72 \text{ in.}$$

Length of stroke = $10.72 \times 1.5 = 16.08$ in.

The size of the engine for this case is, therefore, 10½" × 16".

The production and consumption of coal is so closely associated with that of pig iron, and of manufactured iron and steel, that it is worth while to note what effect the record for 1899, made by these commodities, will have upon the total mineral production for 1899. The production of pig iron in 1899, was 13,700,000 long tons, against 11,773,934 long tons in 1898. The average price for pig iron in 1899 was about \$18 per ton, making the total value about \$246,600,000 against \$116,557,000 in 1898 when the average price was less than \$10 per ton. This makes an increase of \$130,000,000, and the increase of \$51,000,000, in the value of the coal product makes a total increase of \$181,000,000, which without any increase in the other mineral production would make the total value of the mineral products in 1899 about \$860,000,000.—United States Geological Survey.

FIG. 5.

NEW INVENTIONS.

EDITED BY H. M. LANE, M. E.

Complete specifications and drawings for any of the following patents can be obtained from the COMMISSIONER OF PATENTS, WASHINGTON, D. C., at the following rates:

Single copies.....	5 cents each.
Copies by subclasses.....	3 cents each.
Copies by classes.....	2 cents each.
An entire set of patents.....	1 cent each.

CORE LIFTER FOR DIAMOND DRILLS.

No. 650,686. G. LEASK, NANAIMO, CAN. Patented May 29, 1900. This invention relates to a special form of core lifter for diamond drills, which is illustrated in Figs. 1 to 3. The crown or bit is shown at 3, and the core barrel at 2.

At the upper end of the core barrel a small block 6 is arranged, through the bottom of which are a series of openings 10, which may be closed by a valve 12. Sliding into this piece 6 there is a plug 14, the upper surface of which is intended to receive the ball 17. The piece 14 is supported by the spring 15. The core is secured by means of the pins 19, which work in inclined slots in the core lifter between the bit and the core barrel, as shown in the illustration. Ordinarily these pins are held almost entirely within the metal of the core lifter by means of the springs 9. During ordinary drilling the ball 17 is removed, the water passes down through the center of 14 and 6 and through the openings 10 into the core barrel in the ordinary manner.

When a sufficient amount of drilling has been accomplished so that the core barrel is probably filled, the ball 17 is dropped down through the rods. It closes the opening in 14, after which, by continuing the water pressure, the spring 15 will be compressed until the ports 8 are uncovered, after which water will flow down through the opening 7, depress the piston valves 20, compressing the spring 9, and forcing the pins 19 out against the core, as shown in Fig. 1. As soon as any strain is brought upon the rods to remove them from the hole, the friction of the core tends to draw the pins 19 still farther out and thus lock the core so as to break it off and remove it. When drilling is being carried on in coal or other friable material which would be liable to be washed away by the large amount of water passing through the core barrel, the valve 12 is closed and the water passes into the ports 8² down through the passages 8³ directly to the bit or crown, thus protecting the core in the core barrel from the action of the water.

WINDING-DRUM INDICATOR.

No. 652,546. WILLIAM F. MURRAY, SAN FRANCISCO, CAL. Patented June 26, 1900. This invention relates to winding drums in which the

drum turns upon a shaft and to which power is applied from the shaft by means of a friction clutch. It consists of devices connected and operated directly from the drum upon which the rope is coiled in hoisting so that the amount of rope wound upon or unwound from the drum will be accurately indicated independent of any slippage or lack of unity of action between the drum and its driver.

A is a shaft to which the power is transmitted from any suitable

motor, and 2 is a wheel or driver fixed upon the shaft and revoluble with it. This wheel or driver has the frictional rings or equivalent devices projecting from one side near the periphery and adapted to engage with or be disengaged from a corresponding engaging portion 4 of the winding drum. This drum turns loosely upon the shaft A, and by suitable mechanism operating in line with the shaft the frictional surfaces may be forced into contact with such pressure that a sufficient power is communicated to rotate the drum. By relieving the pressure the drum may be allowed to turn independently of the shaft without stopping the motion of the latter, and the cage can thus be lowered. Any suitable brake mechanism may be employed to control the movement. 8 is a plate or disk bolted upon the end of the drum having suitable lugs and bolt holes being centrally perforated to fit over the hub and central portions of the drum. This plate or disk has a cylindrical sleeve projecting outwardly from it and carrying the threads of a worm-gear 10, and this worm engages with the teeth of a corresponding gear-wheel 11, which turns a shaft 12, and by the mechanism shown the pointer 16 is worked in front of the dial plate.

PIG EJECTOR.

No. 650,596. F. L. WHITE AND M. G. SEMPLE, PITTSBURG, PA. Patented May 29, 1900. This patent covers a device for removing pigs from metal moulds which are arranged in a continuous line between sprocket chains, and the general principle is shown in the accompanying figure, in which 3 represents one of the moulds between the sprocket wheels 2. Opposite the center of the sprocket wheels are arranged two cylinders 4, in which work piston rods 5 carrying hammerheads 7. The pistons are operated by any suitable fluid, as air or steam, which is conducted to and from the valves by pipes 11 and 12, from the rotary valve 23 which is placed upon a continuation of the shaft 19 carrying the sprocket wheels about which the moulds pass. 22 is the main fluid supply pipe and 24 the exhaust pipe. Ports are arranged in the valves

so that the fluid is pumped through first one and then the other of the cylinders 4, so that two sharp blows are struck near the opposite ends of the pig in the mould, one blow being struck just in advance of the other, thus loosening the pig and driving it out of the mould. The cylinders 4 are mounted upon trunnions 8 and maintained in place by springs underneath, which can be adjusted to give the hammers 7 any desired elevation. The object of the springs is to return the hammers to their place when they are dragged out of position by any pig leaving the moulds. In the form shown the pistons are cushioned at the end of the stroke by fluid introduced through the pipes 15 and 16, though the patent also covers the alternate device for cushioning by means of springs.

COAL-DUMPING APPARATUS.

No. 654,019. JOHN M. PHILLIPS AND JOHN J. FLEMING, PITTSBURG, PA. Patented July 17, 1900. In an automatically dumping tipples it has been customary heretofore to provide dropping crossover-rails, which were attached at one end to the swinging or tilting platform, and at the other end were hinged to or rested on the stationary framework of the tipple structure, so that as the swinging platform dropped down the dropping rails went with it, preserving, however, their alignment with the rails on the tilting platform and the stationary rails beyond. The dropping rails being thus always maintained in position below the end of the car, were to some extent in the way of the falling coal, and it would frequently happen that lumps of coal striking the dropping rails would, instead of falling into the chute or screen, fall over the outside of the dropping rails and onto the ground below. This invention dispenses with dropping rails and provides crossover rails of novel form, which upon the dropping of the tilting platform, are automatically swung entirely out of the path of the falling coal, and which automatically resume their position in alignment with the rails of the tilting platform as soon as the latter has resumed its horizontal position. Fig. 1 is a plan view of a tilting tipple. Fig. 2 is a vertical longitudinal section of the same, and Fig. 3 a transverse sectional view on the dotted line Fig. 1. The tilting platform is mounted on the tipple structure. Plates or blocks serve as rocker-bearing surfaces upon which are rockers, which serve as the fulcrum of the tilting platform or tipple. The car-stops FF are secured to rock-shafts G, which rock

and move the horns out of the way of the wheels of the car by mechanism under the control of the tippie operator. Beyond the timber *A*, and in substantial alinement therewith, heavy timbers *H* are arranged, being a part of the tippie structure, and upon the inner sides of the timbers *H* are rocking-shafts *II* journaled in the eyes *ii*. The cross-over rails *LL* in their normal position of alinement with the rails of the tilting platform, rest at one end upon a bar *M*, on the tilting platform, and at their other ends rest upon a cross-beam *N* of the tippie structure. The rails *LL* are rigidly connected with the rock-shafts *II* so that as the rock-shafts turn or rock the rails *LL* will swing outwardly until they are entirely out of the way of the coal which falls from the car.

An inspection of Fig. 3 of the drawings, shows the parts in their normal position in full lines, and in the position which they assume when the platform is tilted, in dotted lines. The rock-shafts *II* extend beyond the inner ends of the crossover rails *LL* and alongside the tilting platform *D*, and are provided with curved bearing-plates *PP*, with which contact rollers *RR*, secured in suitable bearings on the bottom of the tilting platform *D*. The rock-shafts *II* are provided with hangers, Fig. 3, to which are attached springs *TT*, the purpose of

which is to return the rock-shafts and the crossover rails to their normal position, after the tilting platform has assumed its horizontal position.

When a loaded car runs onto the tilting platform it is stopped by the horns, or stops *F*, in such position relatively to the rockers that the weight of the car and its load will overbalance the tilting platform, which is allowed to tilt by releasing a brake that works against a curved depending sector *U* at the rear end of the tilting platform. As the tilting platform tilts, the rollers *RR*, bearing against the curved pieces *PP*, rock the shafts *II* and swing the rails outwardly until they have assumed the position shown in dotted lines in Fig. 3 of the drawings—that is, to each side of and entirely away from the space through which the coal falls from the car to the chute or screen. When the coal has been dumped upon the chute or screen, the tilting platform, being weighted at its rear end, resumes a horizontal position, and as its forward end rises, the crossover rails swing back into their former position in alinement with the rails of the tilting platform, being assisted by the spring *T*. The stops *F*, being now moved out of alinement with the wheels of the car, the latter is run over the crossover rails *LL* and onto the stationary track beyond, from whence it is switched onto a parallel track and taken back to the mine.

TRIPOD AND CLAMP FOR ROCK DRILLS.

No. 653,306. WILLIAM K. MILHOLLAND, CHICAGO, ILL. *Patented July 10, 1900.* This invention relates to the means for joining the several legs and head of a tripod and for adjustable clamping and slide frame for the cylinder of the drill to the head of the tripod.

A B are the front legs of the tripod and *C* its rear leg, the latter being bifurcated at its upper end, having the two arms *cc*, each of which is provided with a journal-box *M*, having a cap *m* secured thereto by means of bolts. The leg *C* is, by means of the boxes *M* and their caps, pivoted upon a sleeve *E*, mounted upon a shaft *D* and in screw-threaded engagement therewith, as shown at *d*.

The front legs *A B* are pivoted upon the shaft *D* at the opposite ends of the sleeve *E* by means of hip rings *FF*, and pivot bolts *GG*. The extreme ends of the shaft *D* are threaded, and nuts are fitted thereto, washers being interposed between these nuts and the hip rings *FF*, so that as the nuts are turned up the hip-rings are forced against the ends of the sleeve *E*. The ends of this sleeve are beveled, as shown, and the hip rings *F* are correspondingly recessed, so that a conical bearing is secured and the parts may be very readily locked together by the application of pressure in turning up the nuts. Each of the hip rings *F* is thus secured independent of the other, so that either one of the front legs may be adjusted without the collapse of the tripod, the other two legs being secured. It will also be seen that the adjustment of the rear leg *C* may be accomplished without loosening either of the front legs. By this arrangement the tripod becomes much more easily managed than when, as is usual in such devices, the loosening of one leg results in the loosening of one or both of the others.

A disk *H*, integral with the sleeve *E*, is located between the arms *cc* of the rear leg *C*, and its periphery is V-shaped. The saddle-block *K*, having a semicircular base *k*, internally grooved, rests and slides upon

the disk *H*. A semicircular locking-strap *O* is pivoted to one end of the part *k* and is provided with an internal groove adapted to the periphery of the disk *H*. A draw-bolt *P* is pivoted to suitable lugs projecting from the opposite end of the part *k*, and the clamping-strap *O* is provided at its free end with a pair of lugs, between which the bolt *P* is adapted to enter, so that a nut *Q*, applied to the end of the bolt, may be turned up against the rearward faces of such lugs, so as to securely clamp the parts *k* and *O* about the disk *H*. This clamping device being loosened, it will be seen that the saddle-block *K* may be moved to any desired position, thereby changing the pitch of the drill-cylinder.

The upper portion of the saddle-block *K* is in the form of a flat round table having its edges beveled inwardly and downwardly, and the slide frame *R*, adapted to carry the drill-cylinder (not shown), is provided with a foot-block *r* of like form, its edges being beveled upwardly and inwardly.

A circular clamp *S*, comprising two semi-circular members *s* and *t* joined together, as shown at *T*, and having an internal V-shaped groove, is adapted to encircle the table of the saddle-block *K* and the footpiece *r*. When this clamp-ring is loosened, the frame *R* may be turned to any desired angular position, and by tightening up the ring

it may be securely clamped in such position. The form of the ring and of the parts clamped thereby is such that by a wedge action the contacting faces of the foot *r* and the table of the saddle-block are drawn together, the groove of the clamping-ring also binding tightly against both parts, so as to prevent rotation.

LIMONITE ORES OF PENNSYLVANIA.

Their Composition and Forms and an Account of the Various Places Where They are Mined in the State.

Written for MINES AND MINERALS, by T. C. Hopkins, Ph. D.

Pennsylvania has always been the greatest iron-manufacturing state in the Union and except during the last decade she has been the greatest iron ore-producing state. But in recent years many of the iron manufacturers have found it more profitable to use ores shipped from Lake Superior than to use those mined in Pennsylvania. Hence a great many of the Pennsylvania ore mines have ceased producing, not because they were exhausted but because they could not compete in quality and price with the lake ores. However, not all the ore mines stopped producing and many that did stop for a time, are again in operation to a greater extent than any one would suspect who has not been over the region.

The history of the iron ore industry in Pennsylvania is an interesting and important one, but the object of the present paper is to discuss certain economic features of the present condition of one of the most important classes of ore, namely the limonite. The hematite and carbonate ores have been important sources of iron in the state; the magnetite ores have been and still are important, but the limonites have been produced in larger quantities than any of the others, possibly because they are more widely distributed and more easily mined.

The limonite ores occur in every county in the state of Pennsylvania, but in only a comparatively few counties are they mined at present. They occur in strata of every geological horizon, but practically all the ores mined at present come from a series of limestones and slates known as the Cambro-Silurian, or, as they are now frequently called, Cambro-Ordovician. The lower portion of the series consists of slates, quartzites, and some limestones carrying fossils which indicate Lower Cambrian age; the upper portion of the series contains Trenton fossils of the Ordovician period. The middle portion of the series is almost barren of fossils and since it is not possible to readily or sharply

separate the groups they are usually referred to as the Cambro-Ordovician strata. The limonite ores which occur in the Silurian, Devonian, and Carboniferous strata have scarcely any commercial importance at present and our discussion refers wholly to the Cambro-Ordovician ores which occur in the limestone valleys of eastern and central Pennsylvania and in the slates and quartzites of the South Mountain area. It should be remembered, however, that the ores occur on and not in these strata. The ores have all accumulated since the folding of the strata in late Carboniferous time and probably very largely since the Appalachian uplift in Cretaceous times. The process is still going on and part of the ores have been formed very recently.

Composition.—The ores are commonly referred to as limonite or brown hematite (the miners frequently shorten it to hematite), but the term must be used in a rather broad or lithologic sense,

meaning the hydrous ferric oxide, rather than as a strictly mineralogic term meaning a definite combination of the iron oxide and water in the ratio of 2 to 3. As may be seen from the following analyses the ores have a complex and variable composition. Besides the iron and water there is always a considerable percentage of silica and alumina, a variable percentage of manganese, and a small per cent. of lime and sulphur. These are commonly called impurities, but some of them are always present and are as truly constituents of the ore as the iron itself. They are found in the purest and most carefully selected specimens, and are not separable from the iron oxide by any mechanical means.

The three common mineral forms of the hydrous ferric oxide

are limonite $2Fe_2O_3 \cdot 3H_2O$; göthite, $Fe_2O_3 \cdot H_2O$; and turgite $2Fe_2O_3 \cdot H_2O$, and the less common form xanthosiderite $Fe_2O_3 \cdot 2H_2O$. It is not always possible to tell whether the commercial ores, commonly called limonite, are admixtures of the above in varying proportions, or whether new compounds are formed with the iron and water in a different but definite proportion. Nor is it possible to determine always the mineral composition of the other constituents. Part of the silica appears to be chemically combined with the iron as the ferric silicate, but whether as anthosiderite $2Fe_2O_3 \cdot 9SiO_2 \cdot 2H_2O$ or chloropal $Fe_2O_3 \cdot 3SiO_2 \cdot 5H_2O$ or some other form has not been determined. The alumina

HUNTER ORE BANK, NITTANY VALLEY, SHOWING OCCURRENCE OF ORE IN EROSION CAVITIES IN LIMESTONE.

evidently combines with the silica, but whether as kaolin or in some more complex molecule is not known. The phosphorus may combine with either iron or alumina as hydrous phosphate. Since wavellite, an aluminum phosphate, has been found at several ore pits, it is thought that possibly a considerable portion of the phosphorus occurs in this form.

I have selected four chemical analyses and computed the hypothetical mineral composition by putting all the phosphorus into wavellite, the remaining aluminum into kaolin, and the remaining silica into anthosiderite. By computing the phosphorus as dufrenite and the silica as chloropal, it brings out a little different ratio for the remaining iron and water.

Form of the Ore.—The ore occurs in a great many different forms which might for convenience be divided into the following classes: 1. *Nodular ore*, which includes the so-called bomb-shell or pot ores and occurs in nodular rounded masses varying in weight from a few ounces to several hundred pounds. These masses sometimes include fragments of chert or sandstone or slate, sometimes a mass of soft clay and in some instances they are filled with water and sometimes are entirely empty. These ore shells are sometimes formed by the deposition of the iron oxide on rock fragments which is shown by the occurrence of these in the various stages of formation from the rock fragment with a thin coating of iron oxide to those in which the iron coating becomes thicker and thicker. As the iron shell increases in thickness, the inclosed rock softens and disintegrates until there finally results an iron shell inclosing loose clay or sand or it may be entirely empty. Some of these ore shells are nodular segregations in slate or limestone when the iron oxide replaces the original rock. Some of these have been found in the slate beds and still retain the lamination of the slate and enclose laminated clay. There has been a deposition of iron oxide

Illustrating Mode of Occurrence of the Ore in Limestone.

in the interior of some of these shells since they were first formed, as shown by the fibrous layers and the mamillary interior surface and conclusively by numerous small iron oxide stalactites found in some of them.

(2) There are two types of *pipe ore*, one consisting of large pipes in which the ore has apparently been deposited around some foreign body, probably calcite stalactites which have subse-

quently leached out. The other form of pipe ore consists of smaller, nearly solid pipes that have evidently been formed in a cavity. It is more common and abundant and likewise a purer ore than the first type.

(3) The *brecciated ore*, one of the most common forms, consists of irregular more or less cellular fragmental masses formed commonly by the deposition of the iron oxide as a cement in a loose mass of fragmental chert, limestone, sandstone, or other

SECTION OF ORE BANK AT HENSINGVILLE, PA.
Illustrating Mode of Occurrence of the Ore in Slates and Clay.

material. There is probably more or less replacement of the rock material by the iron, as in the case of the first class which it resembles in many ways. Frequently the inclosed rock fragments have disintegrated and have been leached or filtered out, leaving the cellular ore. Sometimes the rock fragments remain in which case the ore is so highly siliceous as in many cases to have little commercial value.

(4) *Sheet or flake ore* is a form that occurs in the joints or seams of the slates or limestones, generally in comparatively thin irregular flakes. It has commercial value only when the inclosing rock has completely disintegrated so that the ore can be easily separated from the other residual material.

(5) *Fragmental ore* is the form in which most of the preceding are commonly found and the fragments are frequently so small that the original form of the ore can no longer be determined.

(6) *Yellow ochre*, while not strictly an ore of iron is the most common form of occurrence of the iron oxide. It consists of the finely divided iron oxide disseminated through the clays, and occurs associated with the ores where they are present and in many places where the ores are absent. It is used to some extent for mineral paint.

Mode of Occurrence of the Ore.—The ore occurs intermixed with clay, sand, chert, and other residual materials (1) in eroded cavities or pockets in the upper part of the limestone, (2) resting upon or against masses of residual white clay, (3) lying upon beds of sandstone, or sand resulting from the same, (4) occasionally in the bedding and joint seams of the limestones or slates.

The areal extent of the single ore deposits varies from a few square yards to many acres. The Scotia mines in Nittany Valley have been worked over an area of more than 100 acres and the limits have not been reached. The deposits vary in depth from a few feet to several hundred. Many of the ore pits are not worked beyond a depth of 80 or 90 feet owing to the expense of lifting the material from a greater depth and of keeping out the water. The actual depth of ore in a few places is surprisingly great. Thus at the Lehman mine in Cumberland county, the record of a boring gave 340 feet of ore, underlain by 40 feet of blue clay, 30 feet of white clay and 20 feet of "Mountain clay," 435 feet in all. At Lambourne in the Nittany Valley, a boring 766 feet shows 300 feet of ore and clay, 450 feet of sand and 16 feet of limestone. Theoretically the maximum depth of the ore deposit is the level of the master stream draining the area. Not many extend to this depth and a few apparently extend below it.

Lesley and Prime, 2nd Penna. Geol. Surv., Final Report and Reports D and DD., both emphasize the statement that the ore occurs in regular belts along definite horizons. Rogers' Geol. Surv. of Pa., 1858, Vol. I, says the occurrence of the ores is empirical and bears no very close relation to the underlying rock except in the Kishacoquillas Valley where he finds that the ores occur over the anticlinal axes in the fissures produced by the flexures of the limestone.

The conclusion of the writer is that ore deposits may occur at any horizon on the limestones, as may be seen by field examination or by consulting the maps of the ore pits in Lehigh, Berks, and Center counties, but since the location of many of the ore deposits is determined by the beds of hydromica slates or the white clays resulting from their decay and since these are generally of considerable extent, there is, where these intercalary slates or clays occur, a tendency to alignment of the ore deposits following the clay belts. This is well illustrated in the map of the South Mountain ore pits in Cumberland county (see Annual Report 1886 Pt. IV 2nd Pa. Geol. Surv.). A bed of sandstone intercalated in the limestone may bring about the same result (see map of Center Co. Report, T, 2nd Pa. Geol. Surv.). In limestone areas where the slates and sandstones are absent there is no

definite alignment about the ore deposits (see Lehigh county map of the ore pits).

Origin of the Limonite Ores.—The source of all the iron and the mode of its accumulation into the ore pockets are interesting and difficult problems which confront the inquiring geologist. Iron is one of the most widely distributed elements in nature; in fact it is so universally distributed that no rock mass is entirely free from it, but it is more abundant in some than in others. All of the strata associated with the ore deposits contain iron, as shown by chemical analyses, ranging from a fraction of one per cent. to six or eight per cent. The ores are produced by the segregation of this diffused iron into the commercial deposits.

SAMPLES OF LIMONITE ORE.

Pipe and Brecciated Ore, one Piece near the Center Shows Sandstone Fragment Incrusted with Ore.

It does not follow, however, that the strata are all of equal importance in the quantity of iron supplied to the ore deposits. The greater part of the iron is thought by the writer to come from the Cambro-Ordovician limestones, and their included slates because (1) most of the ore deposits occur on the limestone areas or on the slates immediately below the limestone; (2)

the limestones contain iron in sufficient quantities to supply the ores; (3) the mode of disintegration of the limestone, which is almost wholly by solution, is most favorable to the accumulation of the iron into the form of ore and its preservation. Shales and sandstones weather away almost wholly by mechanical erosion and most of the iron contained in them would be carried away with the sediments. One might question at first thought the adequacy of the supply when we consider that the analyses of the limestone show only from one to five per cent. of iron. But if we consider that one per cent. of iron means a thickness of 40 feet of iron ore in 6,000 feet of limestone, the supply does not seem so small. However, we should compare the iron with the other insoluble material of the limestones, in which case we find that the iron averages about 24% which is up to the average of that in most of the ore pits. Any mathematical calculation on this line must be indefinite because in the first place we cannot tell how much iron is carried away by the streams, nor what per cent. of it is diffused through the clay as ochre; on the other hand there is (1) considerable lateral segregation of the iron as shown by the barren areas between the ore deposits, and (2) in the highly folded strata (nearly all the strata are sharply folded) the thickness of limestone eroded over any ore deposit may be much greater than the normal thickness of the limestone at that place.

Some of the iron of the ores is derived from the shales and slates overlying the limestones but only a comparatively small part. Some is derived from the underlying Cambrian slates but the bulk of it comes from the limestones. The ores are formed by the segregation of the iron into solid bodies partly (1) by replacement of the original rock material, (2) in cavities in the limestone, (3) in the joint and bedding seams of the limestones and slates, and (4) by deposition on the rock fragments at the surface or in cavities or on the beds of clay or sand. Sometimes the inclosed rock fragments are retained in the ore, making them very impure and sometimes they have disintegrated and crumbled out. All stages of the process may be observed in some of the mines, from the compact rock fragments and those partially disintegrated, to the iron shells inclosing loose clay or sand and those entirely empty or filled with water. Where the iron is deposited on an accumulation of rock fragments, it may form a considerable ore mass having a brecciated or conglomerate texture, and being very silicious if the rock fragment remain, or quite porous if the inclosed rock fragments have been leached out.

In the northward extension of the Great Valley in New York, the ore has been shown in some localities to result from the disintegration in situ of a highly ferruginous limestone. In the southward extension of the Great Valley in Tennessee some of the deposits are said to be the oxidized portions of pyrite veins. No positive evidence could be found that any of the deposits in Pennsylvania originated in this way.

Development of the ores.—The ores have been mined quite extensively in all the Cambro-Ordovician limestone and slate areas in Pennsylvania, in fact all along the Appalachian range. The

ore pits are scattered indiscriminately over the limestone portion of the Great Valley and the smaller parallel limestone valleys and portions of the slate and quartzite areas. Some of the most productive localities are Iron-ton in Lehigh county, Kline's Corners in Berks county, Boiling Springs and Mountain Creek in Cumberland county, Mt. Alto in Franklin county, Bellefonte, Scotia, and Pennsylvania Furnace in Center county, and Ore Hill in Blair county. The following list of the limonite ore pits has been compiled largely from the maps and reports of the Second Pennsylvania Geological Survey. It includes the idle as well as the operated pits so far as could be ascertained. Some of the pits are small and have produced possibly only a few tons of ore, while some have produced at the rate of several car-loads of ore per day.

Productive and abandoned limonite ore pits of the Cambro-Ordovician areas in Pennsylvania:

County.	
Lehigh	202
Berks	25
Lancaster	27
Dauphin	5
Cumberland	101
Franklin	49
York	157
Center	79
Huntingdon	80
Blair	32
Total	707

Besides the ore pits enumerated, there are a great many in Northampton, Lebanon, Chester, Mifflin and Bedford counties of which no definite figures could be obtained. The list does not include any ore pits that have been opened since the Geological Survey reports were published which was 20 years or more ago for some of the counties. So that probably the total number of openings from which the Cambro-Ordovician ores have been mined in the state is not far from 900.

The production of the ores at present while more than it was a few years ago, is quite limited compared with that in the decade between 1860 and 1870.

In Center county several mines near Bellefonte are in active operation supplying ore for the Bellefonte furnaces. The Scotia mines, the largest in the county, have been in almost continuous operation for many years. Until recently they were controlled by the Carnegie Company but since the spring of 1899 the ore is shipped to the Bellefonte furnaces. The Hunter and Lambourne banks near Scotia are active producers.

The Ore Hill mines in Blair county have been shipping ore for many years. At the present time 100 men are at work mining and shipping ore and clay.

The large ore pits in Franklin and Cumberland counties have been idle for many years except the two large banks of the Reading Iron Co., south of Boiling Springs which began operations shortly before the outbreak of the Spanish-American war, which cut off the supply of Cuban ore from the eastern furnaces. During 1897 they shipped about 3 car-loads a day, in 1898 about one carload per day.

There is considerable activity among the ore producers in eastern Berks county. In the immediate vicinity of Kline's

SCOTIA ORE BANK, SHOWING FACE. STEAM SHOVEL USED IN LOADING, AND BARREN AREA.

Corners (Schweyer post-office) there are 8 ore washers and banks in operation, and small quantities of ore are shipped from ore mines near Albert's Station. One of the 3 large ore mines south of Fogelsville is washing and shipping ore.

Siegers mine at Siegersville was reopened in 1899 and is mining the ore in drifts run in from the sides of the old pit opening. The large Iron-ton mine after lying idle for 13 years

was reopened in the spring of 1899 and shipped ore during the summer at the rate of 3 or 4 carloads per week. At Guth's Station between Ironton and Allentown are two limonite mines in operation, both of which are now worked through vertical shafts, the ore being lifted by steam hoists. The depth of the shaft is 125 feet. About a mile east of Guth's Station is another limonite mine in operation, worked in an open pit 75 to 80 feet deep.

Lerch's ore pit near Bath in Northampton county is producing considerable limonite ore.

The ore mines above enumerated are those I observed in operation in 1899, but it is quite probable that there were some others operated that are not mentioned as my field work did not take me into all parts of the area.

Methods of Mining the Limonite Ores.—In some of the smaller pits the ore has been obtained by digging over the material with pick and shovel and picking out the lumps of ore by hand. At nearly all the larger pits washers have been erected in which the clay and sand are separated from the ore by the use of water. The washers used are the common log washer consisting of a horizontal beam set with short metallic arms and rotating in an open trough into which the material is dumped along with a constant stream of water. The arms are so placed on the shaft as to slowly move the ore and rock fragments forward to an opening in the trough where they drop out, while the stream of water

In a few localities the ore appears to be concentrated along certain horizons under a more or less barren overburden of considerable thickness, so that it is found to be cheaper to mine the ore in underground workings, from which it is elevated to the surface through a vertical shaft, as at Guth's Station, or by an inclined slope, as by the Reading Iron Co., near Roaring Spring.

It is probable that the limonite ores of Pennsylvania will never reach the importance they once had in the market, as they cannot compete with the larger deposits of richer ore in other localities. Yet at the present price of iron, they can be mined profitably for local use in even larger quantities than at present, and the indications are that more mines will be opened in 1900 than there were in 1899.

PERE MARQUETTE MINES.

A Description of One of the Largest and Best Equipped Coal Mines in the State of Michigan.

Written for MINES AND MINERALS, by R. A. Randall.

The Saginaw, Pere Marquette and Verne Coal Companies, located at Saginaw, Mich., are now hoisting twelve hundred tons of coal per day from their four shafts. The Pere Marquette No. 2 is

SURFACE WORKS AT PERE MARQUETTE MINES.

carries away the clay and sand. Formerly jigs were used at some of the larger mines for separating the heavier ore fragments from the lighter rock fragments. At some of the mines this separation was made by hand-picking. At present neither process is used and the rock fragments are shipped with the ore and fluxed off in the furnace. The washers are erected at an elevation of 20 or 30 feet above the surface so that the ore can be dumped from the washer directly into the railway car without rehandling.

In most places the ores are mined in open pits and drawn by cable up an inclined tramway to the washer. In the large pits branch roadways are extended out to different portions of the pit. In the Scotia mine the area worked over is so large that a locomotive is used to move the cars to the foot of the incline at the washer. Commonly the material is mined and loaded on the ore cars by hand but in the Scotia mines this is done by steam shovels of which there are three in operation.*

*See article "Iron Ore Mining," The Colliery Engineer and Metal Miner, Vol. 16, page 101, for details of steam shovel mining at Scotia.

the best equipped shaft in the State of Michigan. Ground was broken for this shaft March 6th, 1899. The dimensions are as follows: Six feet eight inches by sixteen feet in the clear, measuring two hundred and five feet to the coal. It is divided into three compartments; two for hoisting, of five feet one inch, the third being used for an airway and the pump pipes. The sinking was done under the supervision of Mr. John Weaver, the present superintendent of the mine. Three shifts were employed of eight hours each, with seven men to each shift, four in the shaft and three on top. 10" x 10" white oak timber was used, and each set fitted and joined together to resist lateral pressure. The sets are placed twenty inches apart with 6" x 12" bunting timber making the divisions. Between the sets 2" oak plank was used for lagging.

The bottom was opened sixteen feet wide by one hundred and twenty feet in length on each side of the shaft. The coal is worked room and pillar on the double entry system. A pillar of twenty feet is left between the entries. The butt entries are

driven about three hundred feet apart and from them rooms are turned thirty-five feet apart. The rooms are worked twenty feet wide with ten to fifteen feet of pillar between, and are driven about one hundred and fifty feet in length. The coal averages about three feet three inches thick.

The mine is ventilated by an S. B. Stine ten-foot fan, the air being split at the bottom of the shaft, one half being used on each side. An air-shaft is being sunk three hundred feet from the main shaft, which will eventually be used for ventilation as well as an escape shaft.

The mine is drained by ditches, where practicable. The water runs into sumps, and where ditches cannot be used, No. 5 and No. 10 Knowles pumps are installed and the water forced into the main pump at the bottom of the shaft.

Haulage is by mule power. Steel cars are used, five feet six inches long by two feet wide, spreading to three feet and holding on an average one thousand pounds of lump coal. At present the mine is hoisting from six hundred to six hundred and fifty tons of "run of mine" per day, of eight hours.

The top works consists of a tippie sixty feet high to the wheel house, which is eight feet in height and made of slat work to provide for the escape of the air during the winter, when it is forced through the hoisting shaft. From one side of the tippie a building forty-three feet high extends over two railroad tracks; attached to this is the scale house, fourteen feet wide, sixty feet long, and with eighteen foot posts. This covers a fifty-two foot eighty ton Howe railroad track scale. Inside of the main frame, there is a second, constructed similar to the first, of 10" x 10" pine. This inside frame carries a screen, with which this tippie is equipped.

The hoisting is done by a pair of 16" x 24" direct-acting engines, fitted with a double conical drum; the cones, running from four feet at each end to five feet in the center. They are capable of making the hoist of 250 feet in ten seconds, including the dumping of the automatic cages. The coal on leaving the pit cars, passes over a seven-eighths diamond bar screen; the lump is weighed on automatic scales and is passed over a patent shaking screen, where it is separated into three grades, domestic lump, steam lump and slack. The slack passes through seven-eighths by inch and a quarter perforations; the steam lump through four inch holes, and such coal as passes over these holes goes into the domestic lump. Slate and refuse of the mine is hoisted on the cages and dumped into a rock car, which holds ten tons, and is then drawn up a 15° incline by a pair of 7" x 10" geared engines with a thirty-inch drum; here the car opens automatically.

Steam for the entire plant is furnished by one of Wickes Brothers' 200 H. P. vertical water tube boilers.

Two wash houses twelve feet by eighty feet each, have been built for the use of the men, where they change on coming out of the mine. All buildings are heated by steam.

Tunnel Developments at Coeur d'Alene.

Written for MINES AND MINERALS, by W. C. Clark.

The law providing for tunnel site locations has never been taken advantage of to any considerable extent in the Coeur d'Alene, owing to the fact that the ledges generally crop out of the surface at short intervals, and there is little inducement to look for blind leads. Some long crosscut tunnels have been run without finding anything of value not shown on the surface. Thus the Bunker Hill and Sullivan Mining and Concentrating Company is working on a crosscut tunnel at Kellogg which will be two miles long when completed, and nearly a mile and a half has already been run, some of it being nearly 1,000 feet below the surface, where it passes under the Sugar-loaf, southeast from the concentrator, but no ledge has been discovered in it. The Campbell tunnel on the Standard crosscuts for 2,620 feet, but no unknown vein was cut. The Mammoth is running one 3,000 feet long, but it is parallel to the Standard's and so nothing could be expected in it, and the new two-mile tunnel of the Morning mine is as yet in but a few hundred feet. On Sunset Peak Senator W. A. Clark has a 2,600 foot crosscut almost completed, and the only discovery in it was an ore-bearing stringer a few inches wide.

Still there are two remarkable cases of blind leads being discovered here. The first was in the Tiger almost a year ago. The Tiger was the first claim located on Cañon Creek, and was among the earliest to be developed. Except for a little work in early days on the side hill where tunnels could be driven into the ore, it has been worked through a shaft. As the shaft went down the town of Burke grew up around it and all the available ground was located. Still there was no sign of a vein between the Tiger and the Hecla 1,200 feet to the south. In spite of that, when the property was sold to the Buffalo Hump Mining Company a year ago one of the first things to be done by the new company was to put in a diamond drill and explore their ground out of the side lines on either side of the old ore shoot. The shaft was then down 1,600 feet, and in order to catch any blind veins, work was

begun on the 1,300-foot level. To the north in several places the drill was run out as far as the side lines but nothing was found. It was then started south and had only gone 150 feet when a new vein was discovered which the drill showed to be about as wide as the one which had been worked so long, and carrying an ore shoot six feet thick. It was then hunted for on other levels in order to learn how near the surface it came, and the surprising discovery was made that it was as strong 100 feet beneath the surface as where it was first discovered. A crosscut was then run from the 1,300-foot level, and at the time the writer visited the property the ledge had been cut and drifted on either way for 200 feet from the point of intersection, the whole 400 feet showing about the same conditions as where it was first encountered, except that in drifting east there was a gradual widening of the ore body until in the face of the east drift at that time there was 16 feet of ore. The town of Burke was built on the top of this vein, which bore so much ore but 100 feet below, and yet no suspicion had ever been aroused that such a thing existed. The ore now being shipped from the mine largely comes from that vein.

The other case was in the Manhattan, discovered last spring. The claim was an old one on which a shaft had been sunk more than 10 years ago. That shaft was on a narrow vein carrying considerable ore in places, but below the 25 foot level the amount of ore steadily decreased, which led to its abandonment, nothing having been done on it for years except enough to hold the claim. Last fall when Barry N. Hillard took a bond on the Amazon he also secured the Manhattan, the two claims lying side by side, their discovery points being not over 150 feet apart. The ledges ran parallel—as is the case with practically all the veins in the Coeur d'Alene—and when the tunnel was well in on the Amazon a crosscut was started to get under the old Manhattan shaft, to raise to connect with it and thus secure air for the work in the Amazon. Just before making that connection the workmen were surprised by running into an immense body of shipping ore which further exploration has shown pretty conclusively to be a blind vein. The stringer on which the Amazon shaft, or rather incline, was sunk was about 18 inches to 2 feet wide, dipping to the north about 20 feet in the hundred, while the ore body below was 10 to 12 feet thick, dipping at about the same angle to the south. The two came so nearly together that had one more shot been put in the bottom of the shaft the new ore body would have been broken into. No trace of the big shoot has ever been found on the surface.

To the eastward of Mullan, however, there is a region which is untouched, and which will probably never be known unless the tunnel site locator gets in there, as it is covered with bare slide rock to such a depth that there is no chance of getting to the surface of the earth except by tunneling. The region is one which promises much to those who have the courage to develop it, the great mineral belt running through from Cañon creek to the Morning and other mines at Mullan runs into it from the west, while just to the east of it again there is a vast district which shows well on the surface but has been developed but slightly. This region referred to is probably two miles north and south by three or four east and west, and is spread out like a map before the eye of the passenger on the Northern Pacific line between here and Missoula, lying on the north side of the South Fork of the Coeur d'Alene River, while the railroad is winding back and forth climbing the south wall of the same cañon.

A Rat Shutting Down a Central Station.

Rats have been responsible for innumerable troubles with electrical apparatus, from the days of the early electric bells up to the present time, but they do not often do as much mischief as in the instance given below. At a large town in the Midlands, England, whose electrical supply station was worked on a special system of low tension, involving an arrangement in which certain cables entering the station near together had rather a high pressure between them, a certain rat who was exploring the neighborhood underground, ate a piece of the insulation off one of the cables, and then appears to have laid upon his stomach on the bare conductor, where he had eaten the insulation away, while he proceeded to attack the other cable. On biting the second cable while in this position, the rat received a shock which killed him, and he lay there bridging the two cables. As, though his body was of high resistance compared with the conductor, a certain current did pass through his body, which was enough to burn him up, to cremate him in fact, his resistance to the passage of the current gradually became smaller as the cremation proceeded, till at a certain point his body having become practically pure carbon, the short length and comparatively large section offered a very good path for the current, with the result that the fuses, which fortunately were protecting the station, "blew," and the station had to shut down while the cause was being found, which was not altogether an easy matter.—*Colliery Guardian*.

COPPER MINING IN NORTHERN WISCONSIN.

An Account of the Geology, Discoveries, and Development in the Western Lake Superior Copper Region.

Kirby Thomas.*

The subject assigned to me by your program committee, "Copper Mining in Northern Wisconsin," is necessarily somewhat local in its scope and nature. Therefore, I shall make this paper brief and touch only on such general facts as the presentation of my subject requires.

Under the stimulus of high price and the prospect of an increasing demand for copper, the efforts to discover new workable copper deposits during the past two years have almost been equal in interest and geographical extent to the ever continuing search after gold. Every favorable formation has been prospected for the red metal, and as a result, the production of copper hereafter will not be confined to a very few localities. One of the new copper districts which promises to come to the front very soon is the Western Lake Superior district, as the considerable area of Keweenaw or copper bearing rocks in Northern Wisconsin is designated.

Geological Formation.—The Keweenaw formation, in which occurs the copper prospects in Northern Wisconsin, consists of a series of eruptive beds alternating with sandstones and conglomerates, and in its upper division almost wholly composed of detrital deposits interbedded with occasional lava flows. The formation lies above the Huronian rocks and below the Potsdam sandstone of the Cambrian period. The Keweenaw formation in the Lake Superior district was probably laid down in substantially horizontal position at the bottom of the ancient sea. Subsequent earth movements tilted the beds so that they form a great trough or synclinal conforming in a general way to the present bed of Lake Superior. One edge of the synclinal forms Keweenaw Point, Mich., and extends westward across Northern Michigan and Northern Wisconsin, flattening out as it passes into Minnesota. The great Michigan copper mines occur on this edge on Keweenaw Point, at the western end of Lake Superior, both edges of the synclinal being represented by the upper St. Croix valley which was formerly and until recently the outlet of the lake. The northern edge of the synclinal forms the Douglas Copper Range in Northwestern Wisconsin, the hills back of Duluth, Minn., and is exposed along the northwest shore of Lake Superior and on Isle Royale. The lower beds of the Keweenaw formation consist mainly of coarsely crystalline gabbros, from twenty to fifty feet thick. After four or five thousand feet of these flows had spread out in horizontal sheets over this Lake Superior region, the magmas became somewhat different in chemical character, the eruptions more frequent and thinner. These constitute the middle series of the Keweenaw formation and most of the copper mines are located in this division. The upper series consist of alternating eruptives and sandstone or conglomerates.

The absolute identity of the formation in the western Lake Superior district with that in the Keweenaw Point region is proven by the following very eminent authorities. On page 139, Monograph V, of the United States Geological Survey, Mr. Irving, referring to the identity of the eruptive rocks of the St. Croix (Wisconsin) district and the Keweenaw Point formation, says: "This identification is also indisputable; it is so because of the absolute identity in nature and structure of the rocks of the region, and because the Keweenaw belts have been followed continuously from the eastern end of Keweenaw Point, Michigan, to the St. Croix river, Wisconsin. The predominant fine-grained basic rocks of the two regions are so completely the same in mineral composition, even to the alteration-products that thin sections of rocks from the two districts placed side by side are not distinguishable from one another. The rocks of the two regions present precisely the same amygdaloidal, pseudo-amygdaloidal, and compact phases. The amygdulæ are made of the same minerals in both, associated in the same ways. Native copper occurs in the St. Croix valley in the same manner, and with the same associates as on Keweenaw Point. The evidence for all the distance between Keweenaw Point and the St. Croix is just as strong as that ever appealed to prove the continuity of geological formations anywhere. From Keweenaw Point to the St. Croix, the formation has been traced mile by mile." E. T. Sweet, of the Wisconsin Geological survey says, in Volume III of the report of that survey, page 331: "Undoubted Keweenaw rocks are found in Douglas county. * * * They extend entirely across the country, outcropping in a more or less broken line, and forming the well known Douglas Copper Range." Professor T. C. Chamberlin, now holding the chair of geology in the Chicago University,

says (Vol. III, Wisconsin Geological Reports, page 357): "The St. Croix valley and Douglas Range formation is not only the equivalent, as the name implies, of the great copper-bearing terrane of Keweenaw Point, but it is directly continuous with it and forms its southwestern prolongation. It is difficult to assign any satisfactory reasons why an igneous overflow should be richer in a metal at a given point than at any other, and still more difficult to understand how a succession of such overflows, separated by considerable periods of time, should be exceptionally rich in the same region. Theoretically, therefore, there is little or no reason for believing that the igneous rocks of one district are less rich in copper than in other portions."

Development.—The significance of the establishing of the identity of the rocks of the western Lake Superior district with the Keweenaw Point formation gradually filtered down to the laity. The increasing reports of "copper finds" on the Douglas Range led to considerable prospecting, which commenced in earnest about three years ago. The showings were good. Then followed the usual boom and bubble. After some excitement and sorrow, the men who have holdings on the Douglas Range, in the St. Croix district and on the Minong Range, as the exposure of the southern edge of the Keweenaw synclinal in Western Wisconsin is designated, settled down to the serious and hard task of opening up copper mines.

Facilities for Mining.—The whole district is within a few hours' ride of Superior, a considerable city with unexampled railroad and harbor facilities. Roads and railroads make the country easily accessible and solve in advance the important transportation problem. Wood and water and water power are abundant throughout the district. The exposures of the formation throughout Douglas county, Wisconsin, are frequent and prospecting is not difficult. However, a large part of the formation farther east is heavily drift covered. The copper occurs in the amygdaloidal, or porous portion of the beds which dip usually at a high angle. Consequently surface work and trenching is quite satisfactory in showing up a prospect.

Land Titles.—The lands in the more favored localities in this district have been syndicated by local promoters, but well located lands can today be secured for from \$5 to \$10 an acre. The title of the lands in the district is all in individuals and the United States mining laws do not apply.

Local Details.—On the Douglas Range four principal companies are developing today. The Chippewa Copper Mining Company, formerly the North Wisconsin, has a shaft on an ore chute down 200 feet and has done nearly 300 feet of drifting and cross-cutting. This company is controlled in Boston and is satisfactorily financed. The Percival mine has reached a depth of 190 feet and shows a good ore body. The Fond du Lac mine has so far confined its work to surface proving and with very satisfactory results. The company is endeavoring to secure money to sink deep shafts and prove the property. The Culligan Company which was one of the earliest discoveries on the range, has recently been reorganized and is now actively prosecuting development. The Copper Creek mine is also a very good property. A crew has been at work on this location all winter.

The St. Croix district, which is a practical continuation of the Douglas Range, has yielded very rich showings to the prospectors. The land in this range has been bought by the St. Croix Consolidated Mines Company, but as yet no development work has been done. On the Minong Range the only development work undertaken is in Town 43, Range 10, in the southeastern part of Douglas county. Here Mr. Fredrick Weyerhauser, the wealthy lumberman, and some associates have opened up a very rich strike. The preliminary work of proving the property has been done and steps are now underway to install the machinery for actual mining. On both ranges there are many individual prospects of good promise.

Assays.—The Wisconsin Geological Survey made a preliminary inspection of the district last summer (1899). The assays made for the Survey from average samples was as high as four per cent. in native copper. An average sample from the Culligan assayed 4.19 per cent. Average samples from the Fond du Lac gave .39, 1.99, 1.25, 1.37 and 1.21 per cent. respectively. Copper Creek samples gave from .29 per cent. to 1.60 per cent. The Weyerhauser, which was not examined by the Survey, yields nugget copper weighing several pounds. In this connection it should be considered that the Michigan mines give seemingly low percentages, yet are profitable because of the conditions and extent of the ore deposits. The Atlantic mine on Keweenaw Point is paying dividends on an average yield of less than .6 of one per cent rock.

The western Lake Superior district will soon be adding to the world's copper supply. The geological conditions and the prospects actually discovered and proved give reason to believe that the district will yet and soon develop several copper mines, and it may rank along with the Michigan district, world famed for the richness of its copper mines.

*A paper read before the International Mining Congress, Milwaukee Wis., June 22, 1900.

MINING PRACTICE

In Butte, Montana, Copper Mines. Methods Employed in the Various Operations.

Shaft Sinking, Costs, Methods of Timbering, Blasting, Etc.; Drifting, Stopping, and Raising; Hand Drilling, Machine Drilling, Trimming, Haulage, Ventilation, Stopping, Etc.

Written for MINES AND MINERALS, by R. B. Brinsmade, B. S., E. M.

In examining the accepted practice of a western mining district that has been worked for a decade or more, it will generally be found that every means is employed to gain an end, and various apparently insignificant little devices (which, however make for smooth and continuous running) are the result of the survival of the fittest of many attempts to apply other methods and devices to overcome the obstacles inherent in the natural and artificial conditions of the district. Of course, improvements are constantly being made in any progressive camp, but in one whose practice is the product of years of evolution, they come only gradually, and are more often the introduction of some new mechanical invention or the equipment with larger and more efficient machinery, as the production and the depth increase, than a change in the method of handling the ground itself.

Hence, a managing engineer entering for the first time a camp whose practice is well established does well to move slowly, and to thoroughly acquaint himself with all the existing obstacles, and with the manner in which they have already been overcome, before attempting to introduce innovations. An old district like Butte is an entirely different problem for the engineer from a virgin camp like Buffalo Hump, in Idaho, or Republic, in Washington, where the methods applied must be for conditions largely novel. The engineer in a newly opened camp, therefore, must first study the actual conditions as far as his time permits, and the methods then applied must of necessity (whatever his previous experience) be largely tentative, and be introduced with the expectation of modification, or perhaps entire replacement by other ones, as the true nature and requirements of the district develop.

The geology of the Butte district has already been touched upon in MINES AND MINERALS by Prof. Arthur Lakes, and an excellent monograph on the subject is the "Butte Special Folio," published by the U. S. Geological Survey, but I shall say a few words on the subject here.

The nature of the country rock is always a vital point to the miner. The Butte granite is unstable when exposed to weathering either above or below the surface, and decomposes from two causes, disintegration and decomposition. Disintegration causes a loosening of the cohesion between the constituent grains, and this has affected all the surface to a depth of 20 feet or more. Decomposition is due to surface and vein waters and to oxidation and it changes the granite finally into a soft clay-like material; its effects extend through all the fissure systems with which the

granite is filled and also to all exposures in drifts or other mine openings, causing a peeling of the walls that necessitates close timbering. The filling of the old workings even is affected and in some cases it has altered the granite fragments so far that their clayey state affords little support to the vein walls.

The productive copper veins fill a series of parallel fissures in strike easterly and westerly and in dip varying from the vertical to 65°, with the majority about 75°. The veins themselves are

replacement fillings of the fissures, the mineral matter often impregnating the walls, so that while the veins proper are 5 feet to 40 feet in width, 100 feet and over is often profitably extracted. The chief sources of the copper are chalcocite, bornite, enargite, and chalcopyrite, while hematite, malachite, and other oxidation products of iron, copper, and zinc occur near the surface; pyrite, sphalerite, and some rare minerals occur as accessories below, while around all is a quartz gangue.

The leading companies of the district are the Anaconda, owning the Anaconda and the Syndicate groups; the Boston and Montana, with its properties lying east of the Anaconda group; the Rarus, adjoining the Boston and Montana; the Parrot, owning the Parrot and Bellona mines; the Butte and Boston, owning, among a large number of claims, the Silver Bow, Blue Jay, and Gray Rock; the Colorado Co., owning the Gagnon group; and W. A. Clark, who owns the Original, Stewart, and Colusa Parrot. All of the above operators have their own reduction works, and each of the first mentioned four has mines producing 500 to 1,000

tons of shipping ore per day through one shaft. The shipments are divided into first class, or smelting ore containing less than a certain per cent. of silica, and second class the balance of the ore that it is profitable to handle. The first class ore is usually kiln roasted and treated in blast furnaces for a 50% matte, while the second class ore is concentrated by water, the concentrates being roasted in some type of mechanical roaster and then smelted for 50% matte in a reverberatory furnace.

Shaft Sinking.—Some companies do this by contract and some by day's pay. For the large three compartment shafts four miners per 8 hour shift are employed, working either double handed or by air drills. A typical example of the double-handed method was the 3 compartment shaft of the Bellona mine, sunk 500 feet from the surface by contract in the summer of 1898. The price paid the contractors was \$21.50 a foot, all supplies (including framed timber) except powder were furnished by the company, and the hoisting was done free. The shaft was 7 ft. × 20 ft. in the clear and the speed of sinking was as follows: 1st 100 ft. in 29 days*; 2d 100 ft. in 30½ days; 3d 100 ft. in 33 days; 4th 100 ft. in 36 days; 5th 100 ft. in 39 days.

The holes were put in as shown in Fig. 1. The holes marked 1 were the center cut and those marked 2 and 3 the end holes. The usual number of holes was 16 as shown, but 18 were sometimes needed and occasionally 12 to 14 sufficed. The whole depth averaged 4 ft., and the drilling was done by ¾" drill steel and an 8 lb. sledge. The powder consumed varied from 8 to 9.8 lb. per foot. The procedure was roughly as follows: 1st. shift—drilled center out, blasted and mucked; 2d shift—drilled end holes, blasted and mucked; 3d shift—ditto 1st shift.

A new set of timbers was put in about every 5th shift taking usually 8 hours., though it was done in 3½ hours. as a record. The hoisting was done by a small drum hoist and bucket to 200 feet, and for the balance a large flat rope reel engine with cage and car were used.

As an example of air drill sinking—at a certain mine a shaft was to be sunk from a drift on the 1,000' level, some 1,200 feet from the main shaft. The shaft was 7' × 22' in the clear and the contract price was \$22.50 per ft., the company to find air drills and all supplies, but the contractors threw up the contract and it was finally completed at \$25 a ft. The lack of any ventilation except the exhaust of the air drills, and the large amount of water to pump were the factors that caused the large expense.

The plan usually pursued for air drilling is as follows (Fig. 2): Two machines are used the bars being set up respectively at A and A', B and B'. From 14 to 16 holes are usually

* The day given consists of 12 man-shifts.

needed varying in depth from 4 to 7 feet according to ground, rows of holes 1 and 3 being omitted in easy ground and row 3 being used only for very hard rock. Rows 1 to 3 are the cut, and rows 4 to 5 are the end holes. One order of procedure is roughly as follows with three 8 hour shifts of 4 men each. Shift No. 1, Drill whole round and blast cut; Shift No. 2, Clean up cut and blast end holes; Shift No. 3, Clean up end holes; Shift No. 1, Put in one set of timber; Shift No. 2, Drill whole round and blast cut; etc. The shaft timbers are framed to fit on the surface (Fig. 3 shows the timbers of the E. Gray Rock Shaft) and sent down ready to go in. No nails or spikes are used for fastening, except the screws in the guides.

Fig. 4.

FIG. 5

from bottom of shaft. The guides, Fig. 5, of Oregon fir are fastened to wall plates by $\frac{1}{2}$ " $\times$ 7" brass lag screws or by $\frac{3}{4}$ " $\times$ 7" steel screws where shaft water is not coppery. They are put on in maximum lengths of 15' and are inspected and oiled once a week. The oiling by black oil increased their wear at the Silver Bow No. 1 mine from a year to over 2 yrs, the oil preventing the cutting of both guides and cage shoes by the grit. The plumbing of the shaft guides is done by either of three methods, by the three lines *a, a, a*, Fig. 4 by the four lines *a, a, a, b*, or by the five lines *a, a, a, b, b'*. The plumb bobs, with lines up to 100 feet long, are hung on blocks from one of the top wall plates and take the position in relation to the set corners shown in *b* Fig. 4 when the set is correctly placed, vertical slits $\frac{1}{8}$ in. deep having been sawed, when framing the timbers 1 in. from each plumb line position.

Fig. 6 shows the scheme for partitioning the pump compartment at the 1,600 foot level of the E. Gray Rock for sinking. Fig. 7 shows the guide frame for holding the bucket. Some foremen prefer to use a cage and car for sinking and while this obviates the difficulty of frequent trips and admits of faster hoisting, it requires a large hoisting engine, and unless the cage can be used in the middle compartment of the shaft, the muck has to be shoveled farther to reach the car. Great difficulty has been experienced in keeping a shaft true where it cuts a vein fissure, and numerous smashed cages are the result of any irregularity. "Ease" timbers have been generally adopted to enclose the shaft sets through the bad ground, and at the Bell shaft there are ease sets for several hundred feet. These ease sets, Fig. 8, consist of an outside set placed around each shaft wall plate and braced against it by the girts *A*. As the ground moves the girts can be altered in length to keep the shaft sets true. The lagging outside of the ease sets is put on without nails, like that for the shaft sets described above, but as only alternate planks are put in, the loose ground can squeeze through the interstices, and, falling onto the floors placed on girts *A* every 15 feet vertically, can be shoveled onto the cage from time to time by removing some loose lagging of the shaft sets. The shaft set lagging in this construction is nailed to the wall plates. The sinking pump, proportioned to the amount of water to be handled and run by compressed air, is

hung by stanchions to the next to lowest set and has as suction pipe a steel wound rubber hose fitted with a strainer that rests in the sump. Before blasting, the air drills and tools are placed in the bucket and hoisted with the men to the level above.

In the plan (Fig. 9) is shown a partitioning of the pump compartment used at the High Ore and other mines; one division contains the column pipes and the other is fitted with guides on which runs a repair cage, operated by a small independent hoist on the surface. Fig. 9 also shows the connection between the shaft and the station timbers. The size of the stations themselves depends upon the size of the ore body, on the level, the presence of pumps, and the heaviness of the ground. They are usually the same width as the shaft and 9 ft. high, while the posts in a direction perpendicular to the length of the shaft are the same distance apart as in the drifts. For station roofs of 10 to 12 ft. span, 12" $\times$ 12" caps are used (or in heavy ground 12" $\times$ 18" caps). For spans above 12 ft. the variations of tunnel sets shown in Fig. 11 and Fig. 12 are used.

Development.—The shafts are placed 800 to 1,500 ft. apart according to the size of the ore bodies, the ease of maintaining levels to the size requisite for horse or mechanical haulage, and the facility of railroad shipments from shaft locations. The shafts are practically all sunk vertically in the foot wall, which system admits of rapid hoisting, and with such steep dips the cross cutting needed to strike the veins is moderate (at the Blue Jay where there is a 74° inclined shaft with a cage running on rollers on 4" $\times$ 6" wood guides, the guides are worn very fast and the hoisting is slow). From the shaft cross cuts are run north and south to strike the veins. The drifts in veins under 20 ft. wide are run in the vein, and for wide deposits, as in the Anaconda and West Colusa mines, they are run within the foot wall.

Cross Cutting.—The cross cutting and drifting is done by air drills on days pay for 10 hour shifts, though for rush work three 8 hour shifts are put on. The placing of the holes is shown in Fig. 13 for the 12 hole system; for most rock nine holes are ample, the center holes of rows 2, 3, and 4 being omitted. For this arrangement the drill bar need only be set up once vertically as shown. The round of holes is usually loaded and fired at one time and goes off in the order 1, 2, 3, 4. Some of the miners regulate the explosions by cutting the fuse of different lengths and spitting them simultaneously while held together in the hand, and others by cutting all the fuse of the same length and spitting it separately in the required order. The granite in the cross-cuts is usually self-sustaining and the only timber in them is the ties

FIG. 6.

FIG. 7.

FIG. 8.

of 6" $\times$ 8" sawed fir, placed 3 ft. centers; if seams are cut the timbers are the regular drift sets.

Drifting.—The breaking of the ground is the same as in cross-cutting, but the drifts are all closely timbered with square sets; the posts are placed 5 to 5½ ft. apart, and half this distance in very heavy ground. The sets are shown in Fig. 14. The method of inserting is as follows: The sub-sill of odd blocks is first set to grade by a straightedge and level, the sill laid on it, and the floor girts inserted. The posts are then set up and the cap put on;

after wedging them true against the sides and the back the top girts are put in place. The lagging is then put in on back, and at sides if necessary, and dirt filled in behind it. For lagging, round unbarked fir or pine poles 3 to 6 in. in diameter are used except where there is to be stoping overhead, in which case $2'' \times 10''$ plank is used for the back; the floor and the track are then put down. The sets are kept within 10 feet of the working breast and a rise of $\frac{1}{4}$ of 1 per cent. is the average grade from the shaft. The completed timber section is shown in Fig. 15. A drain is left under the sill center and the water from it on reaching the shaft is taken down the pump compartment to the nearest pump by a square wooden drain box. For drifting through running ground, which occurs occasionally, $4'' \times 6''$ spiling is driven ahead over cap of last set, as face is advanced (Fig. 16), until the next set ahead is put in. Then the spiles are blocked up above the cap so that the next series can be driven under them, or the spiles are removed and $2'' \times 10''$ plank substituted. A similar method is pursued in reopening a drift under a stope that has been worked out and filled in, the old timber having to be cut away in addition. Great care has to be exercised to prevent a slide of the old filling, as such an accident is difficult to remedy. The speed of drifting varies with the ground and the manner of working. In the Butte and Boston mines, where the drifts are run by machines and the machine men do their own timbering, the advance varies from 30 to 70 ft. per month; while in the cross cuts with no timbering to do the advance is from 45 to 85 ft. per month. These results are obtained by working 25 days a month with two 10 hour shifts of 2 machine men each; the men do their own shoveling and shove the cars a mean distance of 120 to 700 feet.

Raising and Stopping.—Where the vein is productive, raises are put in every 50 to 100 feet. They are usually 2 sets wide; a manway set for the ladder and the timber chute, the other set is the ore chute. Two ore chutes are put in for wide veins with the manway set in the middle. If the vein is wide enough the raises are carried up in regular square sets, the sets being stepped off towards the foot with the dip of the vein, Fig. 17. The raise sets are the same dimensions as the drift sets, except they are a foot less in height. Stopping can commence in both directions along the strike of the vein as soon as the first raise set above the drift is put in. The chutes are usually put in along the foot wall and stoping for several sets into the hanging can be conducted without trouble. The stope sets are floored over with $2''$ plank and the dirt broken at the face is carried by wheelbarrows and dumped into the chute. As soon as one floor is worked out to the next chute, the flooring is pulled up and used above, and the space filled in with waste from the stopes overhead. The square set system permits of each set being considered a unit,

best practice to leave a pillar *P* (Fig. 18) 6 to 8 ft. below each drift in the vein in order to simplify the maintenance of the drift, as the pillar is easily robbed on abandoning the level. For veins too narrow to admit of the regulation $4\frac{1}{2}$ ft. in the clear, the caps are shortened to $3\frac{1}{2}$ ft. in the clear. Commonly, inclined sets are used as shown in Fig. 20, the sills *B* and *A* being placed perpendicular to the foot wall for the flatter veins. For hard foot walls the foot wall posts are omitted and in some cases only stulls need be employed. The disadvantage of these inclined stulls is the slanting floor that interferes with the wheelbarrow tramming. If only slightly slanting this is obviated by setting the lowest plank horizontal as at *K* (Fig. 21) or if more slanting the whole floor is made horizontal by blocking as *L*, Fig. 21. There must always be left $2\frac{1}{2}$ ft. inside of timber to pass the wheelbarrow. Where square sets are used it is often best to angle brace with *C* and *D*, Fig. 22, and if ground is heavy a counter brace *XY* is needed to prevent collapsing. The cap is usually all one piece, the butt caps *A* and *B* being used only when they are to be replaced by regular caps after further stoping.

The stoping is all of the "back" variety, and each floor is kept at least 2 sets ahead of the floor above. Air drills are used for stoping wherever the vein is 2 sets or more wide and where the larger blasts will not mix the ore and waste too much. Fig. 23 shows the manner of attacking wide stopes, the heading *A* being first driven by one machine. *B* and *B'* are then kept two sets behind *A* by two gangs while two more gangs *C* and *C'* can drive their stopes 2 sets behind *B* *B'* respectively and so on across the stope. The extra filling needed for wide stopes is taken from the crosscut driving, or even from old dumps or special underground country rock excavations. By single hand drilling, two men can easily break and muck $\frac{1}{2}$ set, or 100 cu. ft. of rock per shift, with a wide well seamed vein.

Winzes.—Winzes are seldom used in Butte, for on account of the water to be pumped and the rock to be hoisted they are more expensive than raises. Sometimes, however, where it is wished to explore an ore body below a drift, and there is no drift below to raise from, a winze is sunk on the vein to develop it. In such a case a Bacon timber hoist is set up in the drift above and a steel bucket on skids hoists the dirt excavated. The winze sets are commonly of $8'' \times 8''$ timbers framed as is customary for small inclined shafts.

Hand Drilling.—Since the introduction of air drills double handed drilling is rare, machines being employed for wide, and single handed drilling for narrow stoping and development. In the average Butte rock 2 men single handed do as much as 3 men double handed; double handed being only an advantage in hard rock where 2 men do 2 to $2\frac{1}{2}$ times as much double handed as single handed. In single handed drilling each miner is

FIG. 15.

so that where too low grade the face can be abandoned without interfering with the discovery and extraction of good ore beyond, which will be reached from another floor. Thus in Fig. 18 (where *M* denotes manway and *C* a chute) the spaces *A* and *B* between the two raises proved barren while the remainder has been removed. A plan of the floor Fig. 19, shows an omission of the barren rock in spaces *D* and *E*. It is considered the

FIG. 14.

allowed 12 to 15 drills per shift as an average, the drills varying in length from $1\frac{1}{2}$ to $4\frac{1}{2}$ ft. and being of $\frac{1}{4}''$ octagon steel. The hardest rock encountered is pure quartz, and the next sound granite; one man can drill 5 ft. of flat holes per shift in average ground and 12 to 14 ft. in easy ground. About twice this distance of uppers can be drilled as in flat, and in down holes the sludge reduces the speed. A leather shield protects the driller's hand

for wet holes. For hard ground the holes are 2½ ft. deep increasing in depth to 4 ft. for very easy breaking ground. Fig. 24 shows the manner of drilling for a typical narrow vein stope, where the first and second class ore lies in separate streaks. The holes are drilled and blasted in the order shown

FIG. 18. (LONGIT. SECT.)

FIG. 19. (SECT. OF NN')

FIG. 17.

FIG. 20.

FIG. 21.

FIG. 22.

the second class being cleaned up before the first class is blasted. The holes are cleaned before loading by the customary long spoon.

Machine Drilling.—The Anaconda Co. uses the Ingersoll-Sergeant, and the Boston & Montana the Rand drill, the No. 300 sizes being employed for all purposes. For stoping and raising where the holes are mostly uppers the drill is set on a tripod, for the shafts, drifts, and winzes, the bar is used. The only duplicate parts kept underground are the side rods and springs, to replace other breakages the machines are sent on top. The life of a machine depends on the shell and that averages in Butte 3 to 4 years. The number of bits allowed per shift averages 12 to 15 of 1½" shank of the X type. The speed of drilling is 80 feet in easy, 40 feet in average and 32 feet in hard ground. Before loading, the holes are cleaned with a sound pump consisting of a ½" rod with a rubber ball on end working tight in a 1" steel pipe. The drill bits are thrown when dull down the timber chutes and collected in the drift by the tool boy, but in the Leonard mine the miners bring them to the station at the close of each shift, thus preventing the loss of tools that formerly occurred in the wide stopes. The sharpened bits are left by the tool boy on the station, at each level and thence procured by the miners.

Powder.—40% dynamite from California is used, the ½" dia. for the hand, and the 1½" dia. for the machine holes; it is fired by the ordinary fuse and caps, miners preparing their

FIG. 23.

FIG. 24.

own cartridges. For wet holes the top of cartridge over the cap is covered with axle grease and the paper wrapper tied tightly around it. For tamping, the soft vein clay is used packed down with a 1" octagon stick. Water is all that is used for tamping downward holes. Misfires that cause so many accidents in the Butte district arise principally from 4 causes: I. A previous blast blows off the upper part of another hole, thus taking off the cap, and leaving the residual powder unexploded. II. Frozen powder.

III. A wet cap. IV. Defective cap or fuse (either originally so, or injured during loading). The number of reports is not always a safe criterion, and it is only by examining the hole stumps before beginning to drill that safety is assured. The missed holes are when found freed from their tamping by a loading spoon and a short cartridge with a new cap and fuse inserted is put in, retamped and fired. The temperature as a rule in Butte underground is sufficient to keep powder thawed without artificial heat. At the Leonard mine there is a large central magazine in an old working for powder and another central room for caps and fuse. The powderman carries from the central magazines the explosives to the two auxiliary store-rooms on each level (the fuse room being at least 50 ft. distant from the powder room) keeping in them constantly two days' supply. In the smaller mines there is only the central magazine, and enough to supply one shift is taken and left on each shaft station by the powderman.

Tramming.—The ore before being put into the chutes is selected in the stopes and broken to pieces under two feet diameter. The waste that cannot be used for filling sets below the working is dumped separately into a chute and trammed to fill in a stope below the drift, or even handled on the cage to fill up another part of the mine, or thrown on the surface dump. The construction of a chute is shown in Fig. 25. The carman stands on plank A and with a crow bar raises the plank gate. The cars used hold from 1,500 lb. to 1,800 lb. of second class ore, according to the mine, and are of the standard sheet steel pattern with self oiling wheels of the Anaconda Co.'s patent, or sometimes the ordinary type loose on the axles. They can be dumped in any direction from a turn table on the car truck. In some of the

FIG. 25.

SECTION OF AD.

Anaconda group large cars pushed by two men are used. The track is of 12 lb. per yd. steel T rails usually 20' gauge. It is spiked to 3"×8" stringers in the drifts and to the ties in the cross cuts; no fish plates are used. The shaft stations are always floored with turn sheets of ½"×3'×10' steel, screwed securely to a flat 2" plank floor. The switches, Fig. 26, have no moving parts, the carman jerking the car sidewise to desired track. Horse tramming is employed where the haul is over 500 ft. and there is enough ore to warrant the extra expense of maintaining the drifts to the necessary regularity. The copper water hardens the horses' feet in the Silver Bow mine, so that the hoofs have to be poulticed with linseed and salt for one day each week. A horse will handle 4 to 8 empties and the same number of loads according to grade. On the 400 ft. level in the Silver Bow, where a very steep down grade is encountered for 250 feet, it was found necessary to put in an endless steel rope whose end sheaves were at the side of the track. The upper sheave was provided with a brake wheel, so that the train could be lowered by attaching the cars to the endless rope.

Mechanical Haulage.—A tail rope system was until recently in use on the 1,200 ft. level of the Anaconda mine. This system has now been replaced by a compressed air locomotive with a receiver pressure of 1,500 lb. to 2,000 lb., which seems to have worked well, as several similar ones have been installed elsewhere by the company.

Ventilation.—The system is chiefly natural, and most of the mines are connected to each other underground giving a fine draft. At the face of a drift as A (Fig. 27), the exhaust from the machine drill gives usually enough air. Where a large stope

occurs, as at *B*, and it is impractical to raise to *A*, a blower is placed at *R*, and air is forced through a wooden pipe (detailed in Fig. 28). A similar wooden pipe is used without a blower to ventilate the drift *A* if it is driven by hand, and the end of the wood pipe would for this purpose be flared out to catch the air from the downcast *K*. At the 1,000 ft. level of the Silver Bow mine, a No. 5 Baker blower is run by a Pelton water wheel, turned by drain water piped from the 800 ft. level. As the water would have to descend to the 1,000 ft. level pump anyhow this affects a considerable saving of power.

A downcast raise is usually driven at each end line of the property, and the main shaft being always hot from its enclosed steam column acts as an upcast winter and summer. When a drift is not in use a door *T* (Fig. 27) is put across it to prevent unnecessary short circuiting of air, and trap doors are similarly placed at top and base of the manways. There are two types of downcast intakes at the Parrot mine. The west one is a square steel house, stationary, with a door on each of the 4 sides that can be opened to the prevailing wind, the draft being diverted down by a burlap sheet and the top of the downcast itself covered by wire netting. On the east side, the downcast house is cylindrical with but one door that is turned to the wind by revolving the whole structure on a circular track.

Light.—As is usual in metal mines, the miners use paraffin candles entirely. The drifters and the stopers use 3 to 4 per 10 hour shift and the carmen from 4 to 6 candles per shift, depending on the places occupied. Incandescent electric lights on the alternating current system are used in all stations and along principal drifts; also for the surface buildings. In 1898, in the Parrot mine, the underground stations were illuminated by kerosene lamps hung from a cap. The smaller mines get their electric current from the city wires, but the larger companies have their own independent plants.

(To be Continued.)

The Genesis of Siberian Placers.

The Siberian placers are situated on the north and northeast of a great mountainous plateau. This vast plain, intersected by important rivers—the Wengra, Angara, Yenisei (nearly 3,000 miles long), the Ob (over 2,600 miles), the Lena (more than 2,000 miles), and the Amur (2,600 miles)—still shows traces of great glacial activity. The origin of the Siberian placers, judging from researches made in other parts of the world may be accounted for as follows:

The Silurian or Devonian mud, on account of the auriferous pyrites it contains, most competent geologists agree in regarding as the almost universal source of gold. This was upturned at the period of the formation of the Asiatic ridge, and at the same time was fissured and broken. The fissures, filled with quartz and pyrites torn from the schist by the action of the waters, became the veins already found. Subsequently, the powerful action of the glacial period gave rise to the placers which are now being worked. If this theory of the formation of auriferous alluvia, which has been verified in the other great gold producing countries, prove true of Siberia also, then it is to the south of the localities at present worked that a systematic search for the primitive strata ought to be made. It is known that the Altai contain veins of lead, silver, and copper; numerous specimens of all kinds of minerals have been brought from that region by hunters and foresters. It is in these hills, with their westerly continuations, and in the mountainous mass which strikes out from Manchuria in a northeasterly direction that the wealth of Siberia must be sought.

The chain of the Khingan, "Mountain of Gold," is said to be rich in minerals, and it is doubtless from these hills that the gold in placers of the Ussuri and Amur (lower portion) was brought.—*U. S. Consular Report. Translation from book by Baron de Batz.*

CURRENT MINING DECISIONS.

Prepared for MINES AND MINERALS.

Action for the Conversion of Ore.—Where, in an action for the conversion of ore, an injunction has been issued, in compliance with which the defendant has stored certain ore theretofore mined, it is not entitled to have the value of such ore taken into account in reduction of damages unless it proves such value, and returns or tenders the ore to the plaintiff.—*Montana Min. Co., Limited, v. St. Louis Min. & Mill Co., of Montana*, 102 Fed. Rep. (U. S.) 430.

Vein or Lode Extending under Adjoining Claim.—Possession of the surface of a mining claim is possession of a vein or lode having its apex within the surface lines of the claim, although, in extending downward, such vein may pass beyond the vertical side lines of the claim, and will support an action of trespass for the removal of ore from such vein, beneath the surface of an adjoining claim.—*Montana Min. Co., Limited, v. St. Louis Min. & Mill Co., of Montana*, 102 Fed. Rep. (U. S.) 430.

Grantees in Possession Under Deed Reserving Mineral Rights.—Where a grantor conveyed land containing limestone ledges, reserving from the grant the minerals in the granted premises, and the right to enter to dig and carry away the same, the grantor's heirs are not deprived of their title to the minerals by the fact that the grantees have been in possession, and occasionally burnt a little of the lime deposits on the premises.—*Brady v. Brady et al.*, 65 N. Y., Supp. 621.

Acts Inducing Unnatural Flow of Gas.—Since the right to mine natural gas, where left to the natural laws of flowage, exists exclusively in the owners of superincumbent lands, and such gas is not subject to public appropriation without their consent, they are entitled to preserve it from destruction, independent of the right of the state to regulate it, and may enjoin any act of one owner to induce an unnatural flow into or through his wells which tends to the injury or destruction of the common supply.—*Manufacturers' Gas & Oil Co. et al. v. Indiana Natural Gas & Oil Co.*, 57 N. E. Rep. (Ind.) 912.

Common Property in Natural Gas.—Since the right to take natural gas is common to all surface owners, and the gas does not become the property of any such owners until reduced to actual possession at the surface. Acts 1891, p. 89, prohibiting the use of artificial means to increase the natural flow of gas from a well is not unconstitutional, as a deprivation of property without due compensation, but is a valid regulation for the protection of common property from destruction, recognizing qualified ownership therein.—*Manufacturers' Gas & Oil Co. et al., v. Indiana Natural Gas & Oil Co.*, 57 N. E. (Ind.) 912.

Construction of Reservation of Mineral Rights.—The owner in possession of lands covered with limestone ledges rising above the natural surface of the ground, having some timber thereon and some tillable land, but the chief value of which was manifestly the stone thereon, conveyed the same by warranty deed, excepting and reserving from the grant "all mines and minerals which may be found on the above piece of land, with the right of entering at any time" to dig and carry away the same. Held, that though to construe the exception as referring, under the title of minerals, to the rock, would practically destroy the grant, the exception comprehended the rock, and reserved the title thereto in the grantor.—*Brady v. Brady et al.*, 65 N. Y. Supp. 621.

Allegation of Extralateral Rights.—A complaint which alleges that plaintiff is the owner of a mining claim, and of all the precious metals contained in any vein or lode, through its entire depth, whose apex is within the surface lines of such claim, and that defendant, the owner of a claim which adjoins one of the side lines of plaintiff's, has mined and removed ore from a vein which has its apex in plaintiff's claim, is sufficient, in the absence of a demurrer thereto, to support a judgment in favor of plaintiff for the conversion of such ore, although it does not specifically allege the facts which show that the boundary between the claims of the parties is a side line of plaintiff's claim, beyond which it has extralateral rights.—*Montana Min. Co., Limited, v. St. Louis Min. & Mill Co., of Montana*, 102 Fed. (U. S.) 430.

Deed Conveying Mineral Land Construed.—In compliance with a decree for specific performance of a contract made between the owners of two adjoining mining claims in settlement of a suit brought to determine a disputed boundary between them, the owners of one claim conveyed to the owners of the other the strip in dispute, "together with all the mineral therein contained, together with all the dips, spurs, and angles, and also all the metals, ores, gold and silver bearing quartz rock, and earth therein." Held, that such conveyance had no other effect than to fix the surface boundary between the two claims in accordance with the original contention of the grantee, and did not deprive the grantor of any extralateral rights under the ground so conveyed; such boundary being a side line of its claim.—*Montana Min. Co., Ltd., v. St. Louis Min. & Mill Co., of Mont.*, 102 Fed. Rep. (U. S.) 430.

THE HAILE GOLD MINES

Machinery Used for Concentrating the Ores and for Roasting and Treating Them by the Chlorination Process.

Written for MINES AND MINERALS, by Prof. Arthur Lakes.

The ore coming from the Haile Mines, described in the September issue of MINES AND MINERALS, goes first to the stamp mill and concentration works, thence to the roasting furnaces, and lastly, to the chlorination works.

A large building containing 60 stamps and concentrating tables also contains a Corliss engine, built in Providence, Rhode Island, and used since May 13th, 1885. A revolution counter records the number of revolutions made per week, month, and year. This engine drives all the machinery in the concentrating works, including the 60-stamp mill and a 350-lightpower dynamo which illuminates the whole plant at night. The same engine supplies power for the diamond prospecting General Electric drill; it keeps 20 Embrey table concentrators, four Triumph concentrators, and 5 Wilfley tables in perpetual agitation.

The ore comes to the mill crushed and is discharged into a bin in the center of the back-to-back stamp mill. The ore is brought in three-ton cars by a narrow-gauge locomotive. The cars discharge from their bottoms into an ore bin built like the gable roof of a house, cone-shaped, so to speak, by which form it distributes the ore to 30 stamps on each side of it; thence it passes into batteries by Hendy self-feeders. The batteries have five stamps to each battery; each stamp weighing 750 lbs. and dropping 90 times per minute. Steel shoes are used. The ore is discharged through a 35 mesh brass wire cloth; then the pulp passes over 8 ft. of silver-plated copper plates coated with mercury. There are four plates to each battery, 50 inches long by 26 inches wide. They are the full width of the mortar and are arranged in four steps, each 2 feet long and overlapping the next by 1 inch, the inclination being 2 inches in 1 foot. They are fastened directly to the battery, the tremor caused thereby being rather beneficial than otherwise to amalgamation. These plates are interchangeable. The advantage of these separate plates is that you only need to remove the top plates for cleaning off, then move the three lower plates forward and the top plate then becomes the bottom plate. Whenever the upper plate becomes hard and unfit for amalgamation, it is cleaned of the amalgam and interchanged with one of the lower plates, thus giving, in rotation to each plate a position at the head of the table. Each battery is provided at the screen discharge with an impact plate, not only for amalgamation, but to retard the velocity of the pulp. The plates are cleaned from verdigris with a weak solution of cyanide, and a little potash is sometimes fed into the battery. Phosphate of sodium is used in the mill to keep the quicksilver bright and lively. The inside plates are removed every 24 hours, as duplicate plates are kept on hand, no delay occurs while they are cleaned. A regular "clean-up" is made once a month.

The cam shaft makes 45 revolutions per minute, the cam being double equals 90 lift-drops per minute. These stamps grind 2 to 2½ tons of ore per day (24 hours).

The life of a shoe is about six months, that of a die the same. The amount of water used per stamp is three and a half gals. per minute; average consumption of quicksilver is 0.35 oz. per ton of ore; wear of shoes and dies is 0.5 lb. per ton of ore stamped. Molasses thickened with flour is used as a lubricant to the cams.

The fineness of the mill gold is 880. The ore of the Cross mine uses the inside battery amalgamator and on these inside plates one-third to one-half of values of free gold is caught, the other half or two-thirds on the outside.

After the free gold has been extracted from the material passing over the amalgam copper plates, the pulp is led through launders, or troughs lined with riffles to the concentrating room, where it is distributed over 26 concentrating tables on a lower floor. The pulp discharges into a box, from which it is led off in small launders onto each table, separately. Little gates open or shut on the launders, regulating the amount of pulp given to each machine.

The ores from the Beguelin and Cross mines owing to the difference in contents of sulphurets are milled separately. The Cross ore averages 2%; the Beguelin 7 to 25% sulphurets. The concentrators are of the belt type; the machines make from 192 to 210 end shakes per minute, the length of the stroke being ¾ inch.

The Embrey tables, of which there are 20, are 12 ft. long by 4 ft. wide with smooth rubber belts, which are set at an inclination of 3 to 4 inches and travel 5 ft. per minute, receiving at the same time 192 percussions. The pulp is distributed within 18 inches of the upper end. The concentrates contain 90% pyrite which is pure sulphide of iron, with occasional small traces of arsenic. The average value of concentrates is \$25 to \$35 per ton.

The Wilfley table is of plain wood, the surface covered with linoleum. On this are parallel strips an inch apart; the motion is lengthwise, 240 shakes per minute. The table is inclined, whereby, when pulp is fed onto the table in one corner, through the motion and parallel strips, the heavy material works down toward the higher point, whilst the light gangue passes over into a tailing sluice, the table being so arranged that at the point where the values are discharged a proportion of it, not being clean, is discharged into a small trough leading to an elevator and returned to the table again.

REVERBERATORY FURNACE ROASTING.

Concentrates are brought from the mill on a railroad running above the top of the reverberatories. They come wet from the mine and lie on top of the reverberatories for drying, then they go down through the top arch of the reverberatory on to the upper hearth. The reverberatory is 45 ft. long by 6 ft. wide inside; 7½ ft. high, a double decked or hearthed reverberatory. The ore is worked forward on top of the hearth till the end of the furnace is reached, when it goes on to the lower hearth. It is then worked to the finishing end of the lower hearth to the firebox, and the finishing roast is made and the ore is withdrawn ready for chlorination. Each time a charge is drawn there is a fresh charge added, keeping the furnace continually filled with ore. The English "pan furnace" is from the Mecklenburg Iron Works; a reverberatory 30 ft. long is attached to this. Ore coming through the reverberatory is partly roasted before reaching the pan roaster. The pan is 12 ft. diameter. It is a cast iron frame lined with fire brick. The trough is built out of brick with a canal in it for discharge. A raker rakes the ore out of the canal into a bin and thence to the cooling floor. The pan is rotated by a small engine and belt just below the works. The sulphur, by means of these furnace roastings, is reduced from about 43% to as low as ½ per cent. and the value of the material increased by ½.

Each double hearth furnace is worked by two men to a shift of 12 hours, the output being 2 tons of roasted concentrates per 24 hours for each furnace. The revolving "pan-furnace" is worked by three men per 24 hours with the same output as the double hearth.

The fumes from these furnaces carry off into the air the equivalent of 13 tons of 50 per cent. sulphuric acid per day. The management have investigated the erection of lead chambers, but so far have not considered such an installation to their advantage. The Spence furnace has been tried at the Haile without success.

THE CHLORINATION PROCESS.

We now come to the chlorination process which is of special interest because Mr. Thies was the first to introduce what is known as the "Thies barrel-chlorination process" into this Southern country.

The roasted concentrates are put on the cooling floor and then by a chain elevator hoisted 40 feet to the top floor of the chlorination building. This building is four stories high, containing three chlorination barrels, 11 filtering tanks, two storage tanks and 13 precipitating vats. The ore is charged by cars holding one ton each, through a hopper into the chlorination barrels. From the top floor the roasted material is charged into a chute leading into lead-lined, iron cylinder barrels, each barrel holding one ton of material; 14 lbs. of lead to the square foot is used for lining. The size of the barrel is 44 inches diameter; 66 inches length, with hole on top capped and lined with lead. It also contains a lead valve in order to ascertain whether the necessary amount of free chlorine is present. The full charge consists of 120 gals. of water (to make an easy flowing pulp), 8 to 11 lbs. of bleaching powder, and 12 to 15 lbs. of sulphuric acid, for treating one ton of ore of 2,000 lbs. The chlorination barrel is then hermetically closed and set rolling 14 to 18 revolutions per minute for about three hours. A 5 H. P. engine performs this work, and also the elevation of the ore. The gold is gradually changed into a chloride. The barrels revolve three hours before the gold is extracted. When the process is completed the barrel is opened, inverted, and discharged through a lead-lined semi-circle, in the floor to a filter on the floor below. There are four lead-lined filters to each barrel, their dimensions being 6 by 8 feet by 18 inches deep in front and 17 inches in the back. The bottom is covered with mineraline tiles 12 by 12 inches by 1 inch thick, perforated and having ¼-inch gutters underneath. On top of these is placed a rack of 1½-inch wooden slats 4 inches high and 8 inches apart to hold the gutter bed in place.

The filter beds consist of 4 different grades of quartz, from ¼" to ¾" and topped off with clean washed sand 1" thick making 5 grades of material. On top of the tiling, strips 4 inches wide, 1 inch thick and 8 ft. long are placed five inches apart for the entire width. The strips are to obviate the destruction of filter beds below in cleaning out the charge after the gold has been chloridized.

The ore pulp discharged in the semi-circle is conveyed through what, from its shape is called a "boot" which distributes it over the filter, built to hold one ton of material. This so-called boot works in a circle, movable from one filter to another. It is so set as to discharge in four filters set back to back.

When ore is discharged from a barrel through the boot onto the filter bed, the material contains gold as chloride; after that the discharge pipe leading to the storage tank is opened and chloride solutions come from the filter in a clean yellow state.

From this tank the liquor is carried by hose through holes in the floor to the different precipitating tanks below. The gold in this liquor as chloride is precipitated into a metallic state by addition of sulphate of iron.

Copperas is made at the works from scrap-iron and sulphuric acid. After precipitation is complete, the tank is allowed to remain undisturbed for three days. The gold has then all settled, and the tank is then ready for drawing off by lead spigots. The bottom spigot is for cleaning out the precipitate.

Before emptying the contents of the barrel, the filter is flooded with water to the level of the top of the filter bed to act as a cushion. The ore pulp is washed twice with clear water. The first time enough water is added to stand 4 inches above the surface of the pulp, and the second time the tank is entirely filled. This amount has been found sufficient to thoroughly remove all traces of chloride of gold from the pulp but repeated tests are made of the pulp.

There are twelve filters, four to each barrel. The chloride solution coming from the filters above is conveyed through separate lead pipes to two storage tanks of 120 cubic feet capacity on the second floor and is drawn off from these into the precipitating tanks as required. These tanks are square, lined with lead, and they settle as well as store the material. The precipitating tanks are eight ft. in diameter, 3 ft. high, and made of wood, the interior being coated with asphalt. They are provided with three outlets; the upper one 18 inches from the top; the middle one, one inch above the bottom and the lowest one in the jamb. The gold is precipitated in the metallic state with an excess of fresh ferrous sulphate made in a small lead-lined tank. In warmer weather 48 hours suffices for settlement and in cold weather from 3 to 4 days. The supernatant liquor is drawn off through the two upper outlets in order to prevent any stirring of the precipitates, and passed through a box filled with sawdust to catch any precipitate.

The gold precipitate is drawn from the tanks through the jamb opening into a small lead-lined settling tank, $2 \times 2 \times 4$ ft. After standing 24 hours the supernatant liquor is siphoned off and the precipitate filtered on paper. This is dried and mixed with about half its weight of borax and soda in almost equal proportions and then refined. Should iron salts be present a little quartz sand is added.

There are 13 large tanks, and two small ones for final clean up. These tanks are filled three consecutive times and precipitated before cleaning out the gold. Then the precipitate from the tanks is put into the final clean up boxes, and is there cleaned up by addition of acid and water from whence it is cleaned up and sent to the refinery where it is melted in graphite crucibles and cast into ingots. The gold coming from this department assays 950 to 995 fine. The extraction is 90 to 95%.

The amalgam from the mill is retorted in a typical retort the same as used in silver mines. A cast iron cylinder has an opening in one end for the entrance of amalgam and at the other end the fumes go out through a pipe jacketed with cold water for condensing them. Bullion is smelted with fluxes in black lead crucibles.

Consumption of Coal in France.

Attention is directed to the increased consumption of coal in France. In 1899 the consumption amounted to 45,600,000 tons, the production being 33,300,000 tons, and the imports 12,610,000 tons. In 1898 the consumption was distributed in the following manner:

	Tons.	Per Cent.
Mines.....	2,860,000	6.49
Metallurgy.....	7,757,000	17.95
Industrial Machinery.....	8,643,000	19.96
Railway.....	5,105,000	11.80
Sea navigation.....	425,000	0.99
Inland navigation.....	37,000	0.09
Works, household, etc.....	18,168,000	42.70

In 1899 the two coal fields of the Pas-de-Calais and the Nord produced together 20,533,671 tons from 124 pits. The Pas-de-Calais produced 14,501,603 tons from 77 pits. The outputs of the largest collieries in tons were as follows: Lens 3,065,611, Courrières 1,930,868, Bruay 1,624,331, Bullay-Grenay 1,486,303, Noeux 1,335,562, Lievin 1,153,512, Marles 1,127,465, Douerges 1,044,240. In the Nord coal field the most productive collieries were, Anzin 3,154,000, Aniche 1,157,412, Escarpelle 724,383.

Care of Boilers.

The question, How to keep boilers clean, is one that vexes all steam users. Scale accumulating in the boiler means a large increase both in the cost of fuel and of the bills for repairs. It takes only $\frac{1}{8}$ in. of scale to require fifteen per cent., and $\frac{1}{4}$ in. of scale to require sixty per cent. more fuel to generate the same amount of steam than with a clean boiler, and as the iron has to be heated to a higher temperature it deteriorates more rapidly. One very common method of overcoming this difficulty is by the use of water heaters.

The "Frontier" heater made by the Ward Heater Co., of Griswold and Jefferson Aves., Detroit, Michigan, is of the open type of heater in which the water is not under pressure, thus allowing certain gases to easily escape from the water.

The heater shell is of $\frac{1}{8}$ -in. iron, and the top and bottom of cast iron. The pans *A* and *B* are of cast iron, as light as strength will permit, and are provided with dams to interrupt the course of the water and expose all of the water to the pans, so that the lime and carbonates may deposit on their way downward. The first pan sets on lugs riveted to the inner shell of heater, with its open edge to the left of door; an *A* pan is next placed in position, with its feet on the upper edge of *B*, and so continuing to the last pan.

The first downward course of the water directs all sand and neutral particles toward the bottom of the mud pot *O*, and all that do not reach the bottom are caught between the mud cells, as they retard the direct outward flow of water. *D* is the outlet to pump for boiler. The inclined sides of the mud pot throw everything to the center, to be blown off as often as required.

There is a large manhole with a self-making joint of square rubber let into a groove in the frame; the door is fastened with bolts, in slots, so that they can be slacked a little, and taken out sideways; this is the only joint made when cleaning, and will last for years.

The water entering the heater is led into the pan *A*, around which it passes through to *B*, and on from pan to pan until it is led by the pipe to the bottom of the heater, in its course being heated by the steam which enters at *F*, till it is thoroughly boiled, and the lime, etc., precipitated to the bottom and sides of the pans. By the construction of the pans the water is continually kept from the direct course of the moving steam, so that the latter cannot carry the water from the heater even though it be overloaded; on the contrary all the wet steam is condensed by contact with the pans and unites with the feed water, and the exhaust passes off as dry steam.

Only sufficient water is admitted to the heater to supply the pump at whatever speed it may run, and enough overflow to carry off the grease and scum. Thus it is economical of heat, in that a large amount of water is not wasted when the pump is running slow. The automatic regulator is simple, has no parts to get out of order, never fails to act promptly. By this overflow at intervals the oil and scum are being continually drained off the top of the water.

A school has been established by the government at Fort Monroe, Va., for the purpose of instructing regulars in the application of electrical machinery used in the army. The rules, published by direction of the Secretary of War, provide that applicants must be under 25 years of age, unmarried, qualified as a gunner, a student of a correspondence school or the owner of electrical books, and no applicant will be recommended unless he has sought for a year or more to become practically familiar with one or more classes of electric machinery or with some portion of the elementary literature on electricity.

ELECTRIC PLANT

At Windber, Pa. A Description of Generating Plant and the Methods of Wiring, Operating, Etc.

By A. S. McAllister.

The modern coal mine bears little resemblance to its predecessor. Increased demands for fuel have required increased rapidity in the methods of handling coal, while business competition has necessitated increased economy in mine operation. The results are that the miner's pick is giving way to machine cutters and the mine mule is sharing the fate of the street-car horse.

In the selection of equipment for mechanical mine operation there enter three factors requiring careful consideration. The first and most important is that of reliability of service; second, flexibility of system; third, cost of equipment and maintenance. At the Windber, Penn., mines of the Berwind White Coal Mining Company can be found one of the most extensive and modern soft coal mining equipments in the world, and here the three requisites just mentioned have been secured by means of electrical and mechanical equipment. Although only two years have elapsed since the first mine was opened, the daily output has reached almost 10,000 tons.

The mines are known as Eureka Nos. 30 to 38, inclusive. The coal lies in what is known as the Miller seam, which at that locality has a thickness somewhat less than 4 ft.

As far as is economically possible, all handling of the coal is done by machinery. Power for operating the mines is derived from batteries of Sterling boilers located at each mine. Capell ventilating fans are driven by steam engines. Ingersoll-Sergeant compressors supply air at 75 lbs. pressure for operating the pumps and coal cutters; 550-volt locomotives are used for haulage, and current from this circuit is used also for lighting the power houses and tipples, as well as the mine proper.

The Phillips tipple equipment used here is the latest type of self-dumping apparatus.

Where the boiler house is situated near the drift mouth, the direct use of steam engines to drive the ventilating fans, avoiding double transformation, possesses obvious economical advantages and this plan is followed. For driving pumps, compressed air has been found to give entire satisfaction. Air pumps require an extremely small amount of attention, and an accidental stopping results in nothing more serious than freezing up. Air coal-cutters are used because they are capable of withstanding all kinds of usage at the hands of inexperienced operators and possess the additional advantage of supplying fresh air at the face of the coal working.

In comparison with electric cutters, air machines are more wasteful of coal and more expensive to supply with power; moreover, pipe lines for compressed air are expensive to install and are usually found unfit to transfer to new openings after having been in use for some time. It was thought, however, that the great reliability of operation and the ease of control by untrained hands more than compensated for these disadvantages.

The first power equipment for electric haulage at Eureka No. 30 included two General Electric 150-kw. 550-volt generators

belted to two 242-h. p. McEwen engines. Increased development soon rendered a third generating unit necessary, and a 150-kw. Thompson-Ryan dynamo was installed. The resistance of the series coils of this machine being much greater than that of the series circuits of the General Electric generators, part of the Thompson-Ryan coils were left outside the equalizer circuit, only as much as were required to equal the resistance of the series circuits of the G. E. dynamos being included between the equalizer connection and the brush. Though of doubtful utility when applied to an ordinary compound-wound generator, this method has given good satisfaction with the machine mentioned. This arrangement is more clearly shown in Fig. 2.

When Eureka No. 31 became sufficiently developed to justify the substitution of electric for mule haulage, a power line was constructed to that mine from No. 30, a distance of 5,340 feet. With a view to future use of the material No. 00 hard-drawn bare copper wires, similar to those in the mines, were used for the transmission circuits.

Eureka No. 32 is situated 6,900 feet from No. 31. Though this mine now has its own power plant, it was considered economical in its earlier existence to transmit power from No. 30. The resistance of the circuit was about 1.67 ohms, one positive wire being run from No. 30 to No. 32 and the negatives from No. 32

connecting to the two negatives to 30 from 31. Though even the maximum short-circuit current at No. 32 could be but little in excess of 300 amperes, it was ascertained that the line was amply sufficient to supply power for one locomotive. Running on this high resistance was but little worse than the use of several sections of the rheostats, as is necessary with the locomotives at the other mines. On account of the intermittent character of the work of each locomotive, the use of two of them at No. 32 caused very few delays on the part of either, though only one could be using current at any given time. Each motorman could easily determine by the brilliancy of the headlights when

FIG. 1. VIEW SHOWING PECULIAR OVERHEAD CONSTRUCTION.

the other locomotive was in use. The establishment of a power house at Eureka No. 32 eliminated this arrangement. It contains two 150-kw. 550-volt General Electric generators direct-connected to McEwen engines. When these units were installed the number of locomotives in use at No. 30 and No. 31 had so increased as to over-burden the three generators at No. 30, so No. 32 was depended upon for assistance. By short-circuiting a portion of the shunts to the series coils of the generators at No. 32 so that they compounded from 500 to 550 volts at full load instead of from 500 to 600 as when first set up, and by altering the transmission circuits so that No. 32 was connected to No. 31 directly through a pair of No. 00 conductors, a fairly satisfactory supply of power for No. 31 was obtained when the generators at No. 30 and No. 32 were operated in parallel.

As now connected the resistance of circuit from No. 31 to No. 32 is 1.07 ohms. With a circuit resistance of .4 ohm between No. 30 and No. 31 and the two power plants running at the same bus-bar voltage, any demand for current at No. 31 is met by the power plants in a somewhat greater proportion than the inverse ratio of these resistances, provided neither No. 30 nor No. 32 mine is using current at that moment. By decreasing the compounding of the generators at No. 30 from 500-550 to 500-525 volts a most satisfactory service for No. 31 has been secured.

FIG. 2. SPECIAL EQUALIZER CONNECTION.

In the early stages of the development of No. 35 a transmission line was run from No. 32, which line now is used only when it may be economical to run only one of the plants. The two plants cannot be run together as is the case with Nos. 30 and 32. Eureka No. 36 is supplied with current from No. 35.

Power for Eureka No. 34 is transmitted over four No. 00 conductors a distance of 2,540 ft. from Eureka No. 33, where are installed two 150-kw. Thompson-Ryan direct-connected generators. By setting the generator circuit-breakers at 475 amperes it is practicable to supply sufficient power to run four locomotives at the two mines with either generator. Some idea of the nature of the demand for power for electric mine haulage may be gained from the fact that, though each locomotive will require, as a maximum, over 300 amperes, 475 amperes will be adequate ordinarily for four locomotives, and six locomotives will seldom require over 600 amperes.

At Eureka No. 37 have been installed two Thompson-Ryan 150-kw. direct-connected generators, and provision is made for a duplicate equipment. The locomotives at Eureka No. 38 will be driven by power transmitted from No. 37.

As has been intimated, No. 00 hard-drawn copper is used for trolley wire. The line construction throughout is of the most substantial nature. In all cases, however, due regard has been had for the fact that numerous changes of location are necessary, as the coal bed becomes worked out. Soldered trolley wire clamps are unsuited to this class of work. Only those providing purely mechanical means of gripping the wire have been found to give satisfactory service.

The locomotive trolley poles must be of such a length as to be easily reversible on a single-track entry, and this sets a limit to the height of the trolley wire outside the mine. The external wiring is supported 7½ ft. above the rails through cap-and-cone insulators by 1½-in. pipe and pipe hangers. The side poles are set 20 ft. apart on each side of the track and 3½ ft. from the rails. To these the pipes are secured by means of cast iron side brackets held in place by ½-in. × 3½-in. lag bolts. See Fig. 1.

Inside the mine the wire varies in height from 39 in. to 7½ ft. The most satisfactory method of suspending the wire from the roof is by means of cast-iron wedges and bolts. For this purpose there are drilled in the roof 1½-in. holes, 6 ins. deep, spaced about 20 ft. apart on straight track and 12 ft. on curves. In these

Quite noticeable in this method of paralleling compound-wound dynamos is the fact that, all other conditions being the same, one generator running at No. 32 supplies more current to No. 31 than both generators do when running connected in parallel.

Power for electric haulage at Eureka No. 35 is developed by three Thompson-Ryan 105-kw. direct-connected generators.

holes ¾-in. × 7½-in. bolts with hexagon heads are secured by means of two roof wedges. Each wedge has a concave inner surface to surround the bolt and convex outer surface to fit the side of the hole when driven home.

The end of each stretch of wire is securely anchored to a special form of roof bolt through a strain insulator and turnbuckle. The use of 18-in. turnbuckles has rendered unnecessary any auxiliary tools for obtaining the required tension upon the wire.

At the air passage overcast on each side entry there is placed a section insulator and switch for disconnecting this section of wire from the rest of the mine in case of accident or extension of the trolley line. Though many types of section insulators were tested none was found which, when exposed to the accumulating moisture of the mine, would not allow the current to leak across in sufficient quantity to render the handling of the partially-insulated wire at least disagreeable, if not dangerous. Application of the scheme of opening the insulator switch and connecting the trolley wire to the rail removes all trouble from leakage currents and has an additional advantage of securing safety from an accidental closing of the switch.

The tracks are laid single on the side entries and double on the main entries. The two main entry wires are interconnected

at each side entry cross-over track. The large amount of conducting material in the main entry obviates the necessity of auxiliary feeders to any portion of the mines; 30-pound T-rails are used on all tracks traveled by the locomotives. On the main entries all four rails are bonded, though the bonding of one rail is considered sufficient for the side entries. The bonds are of No. 00 soft annealed copper secured to the rails by ¾-in. channel pins. It is necessary to use the greatest care in order to obtain good bonding in this way on such a system as the one under discussion.

The effect of electrolysis is quite noticeable, especially upon the water pipes, a case being recalled where a certain section of

pipe required a new union about every three weeks on account of "rust." A slight change in the channel pins by which the concave portion next to the wire could not offer a cutting surface as at present would undoubtedly decrease the number of bonds quite often carelessly sheared. At each mine is located a locomotive house of sufficient size to shelter six locomotives, with pit space for four. The houses are heated by steam and lighted by electricity. The pits are five feet deep and well drained. A 6,000-lb. Harrington chain hoist serves to handle the motors and axles when repairs become necessary.

Two general types of locomotives are in use at the different mines; the General Electric 13-ton, draw-bar pull 3,000 lbs. at

FIG. 3. GENERATOR ROOM AT EUREKA NO. 35.

FIG. 4. CONTROLLER DIAGRAM.

8 miles an hour, and Baldwin-Westinghouse, 26,000 lbs., with a speed of 8 miles an hour.

All of the locomotives in use here are equipped with magnetic blow-out rheostatic controllers, the two series-wound motors of each locomotive remaining always in parallel, and the various speed changes being governed by adjustable resistance in the power circuit, as indicated by the controller diagram, Fig. 4. If it were possible always to run the trips at the maximum speed of the locomotive, this method of control for such service could not be improved upon. Experience, however, has shown conclusively that the trips can very seldom run with safety at such speed and that the major portion of the hauling is done on two of the four sections of the rheostat. Nine-tenths of all electrical trouble experienced with the locomotives at Windber has been due to this fact. A system of control so designed that the light load hauling, switching and trip gathering could be done with the motors in series and the straight track hauling with the motors in parallel would be found much more satisfactory for this class of work.

On account of the motors being always in parallel a mere shifting of the reverse lever when the locomotive is in motion results in an almost immediate stop of the locomotive, due to the generator action of the motors; this effect being independent of any connection to the trolley line. Though this action is of inestimable value when used as an emergency brake, the knowledge of its availability on the part of the motormen has rendered them more careless and resulted in the destruction of many gear wheels. Reversing the motors and throwing the controller lever to the first position has been found to give equally good braking and to have a cushioning effect on the gear wheels.

The slow speed at which much of the heavy hauling must be done has been commented upon. To return the controller lever to the "off" point with a heavy current passing, such as is required, invariably results in vicious arcing at the controller

FIG. 5. DIAGRAM OF ELECTRICAL CONNECTIONS BETWEEN THE THREE GENERATING PLANTS.

tips, which soon carbonizes the insulation. It frequently happens, even, that an arc from trolley to ground in the controller occurs, which obviously throws circuit-breakers and entails delay. In order to obviate this source of trouble the following method of using the controller has been adopted:

If it becomes necessary to throw the controller "off" on a heavy haul at slow speed, first throw the lever forward till the drivers spin, then quickly throw to "off" point. This never fails to give the desired result; that is, a reduction of sparking. The prolonged high speed of the armature generates sufficient counter E. M. F. to reduce the current to a value at which the circuit may safely be opened.

Power for lighting the mines is taken from the haulage circuit, five 110-volt lamps in series being used at the main entry cross-overs and two 275-volt lamps at the single switches. All light and signal circuits are of No. 12 insulated copper wire supported on porcelain knobs secured to wooden plugs in the roof.

There can be no doubt that, with such extensive mine operations as at Windber, polyphase currents for pumps and cutters would be found much more satisfactory and economical than compressed air. The use of 500-volt generators supplying both direct current for the haulage locomotives and polyphase currents for induction motors would, by proper disposition of circuit-breakers and fuses, prove the most economical system for mine equipments, and it seems reasonable to expect that such a plan will be adopted sooner or later.

EXPERIMENTAL ORE TESTING WORKS.

Means for Determining the Proper Method to be Used in Treating Ores From a New Mine—Importance of Tests.

Written for MINES AND MINERALS, by Prof. Arthur Lakes.

There are certain problems that are almost sure to come up with parties who own a prospect or a young mine. They have the mine or prospect examined by an expert. He takes his samples of the veins or vein in the usual way. If the vein is developed along a tunnel or drift he may take his samples across the vein at every ten or twenty feet and after quartering, etc., average up the whole result, but this at best gives but an uncertain and only approximate idea of what the true value of the vein as a whole is. What is desired is to know what it will run day in and day out on an average, and this the assay will rarely prove, or at best only very approximately. In another case the property containing several veins may only be developed by a cross-cut tunnel, cutting across the several veins. On these there may be little or no development and the expert has only a chance to take one assay sample on the face of the vein where it is cut by the tunnel. This gives a very inadequate idea of the possible value of the vein.

Now, what the owner wants, is to have mill runs made of much larger samples than the assayer's—500 to 1,000 pounds at least, or even tons and car-load lots. These, too, should not be taken all from one spot, but if the development is sufficient, at intervals, say of over 100 or more feet apart. This certainly should be done before expensive works or mills are contemplated. Having then obtained a fairly good idea of the quantity and quality of the ore by these large mill tests, another and very important problem arises, viz.: what will be the best process for treating these ores, shall it be smelting, stamping, concentrating or cyaniding? Many a mine and mill has failed from a choice of a process unadapted to the ores. The need felt on this subject has led to the establishment in Denver and elsewhere of small experimental plants whose sole purpose is that of trying large samples and deciding what milling or other process is best adapted for their treatment. The following is an account of a personal visit to the ore testing works of Henry C. Wood, in Denver: The works are located on the Denver & Rio Grande R. R. tracks within the city limits of Denver and are easily reached by electric car line. From the works is a fine view of the distant mountains. The building is three stories high and 100 feet long and 40 feet wide. Railroad track scales weigh the ore on receipt. There are 20 ore bins into which the ore is discharged, giving a total storage capacity of 200 tons. The ore from the bins passes through a Blake crusher, from this when crushed it goes up an elevator to the top of the building, and as it falls into feed bins there is a Vezin automatic sampler, which distributes a fifth of the sample into a sample bin. The main pulp goes into an ore bin. Besides the crusher the ore can be crushed by rolls and stamps, all of it being wet work. There is also a set of rolls for dry work.

After the ore has passed through a Challenge automatic feeder it passes to coarse rolls, then by elevator to revolving trommel-screens for screen sizing through 10 to 16 to 20 mesh. The trommels are changeable for screening different sized material. What goes through them passes into a hopper directly down to the Wilfley No. 1 tables on the floor below. The oversize goes to regrinding rolls and the tailing of No. 1 also goes back to the regrinder and comes up and goes through a forty-mesh screen.

After passing this the remaining product goes down to a shaking 80-mesh screen. On the upper floor, table No. 2 treats only 80-mesh screenings and finer matter. The more you size the product the better is the work done. One table is run on 20-mesh material, another on 80 and finer, a third on intermediate between 40 and 80. The tailings of the 80 mesh go down to the double decked Wilfley table below and so the ore passes over as many tables as possible. Finally, to avoid even a possibility of loss by escaping slimes, outside the building there are "Cornish-frames," consisting of long narrow wooden troughs lined with canvas. As the slimes pass down over this on a slant, they are treated by a hose which drives off the refuse and causes the fine ore to be caught in the canvas.

The middle floor of the building is mostly occupied by Wilfley tables, crushers, and elevators. On the floor above is a hydraulic classifier which gives two classifications. Any gold remaining in the tailings is thrown into tanks for examination by cyanide.

Stamps.—At the south end of this floor is a full-sized modern stamp battery of five stamps, the stamps weighing 800 pounds and having 97 drops per minute. These stamps crush down to 40 mesh or other desired size. Tailings after plate amalgamation run on to

single deck Wilfley and tailings of that go back over the double deck Wilfley table. A combination can be made of three different sizes on these tables either before or after amalgamation, and finally, if desirable, all the tailings can be treated by cyanide. There is an ingenious device for increasing the percentage of gold that can be caught by amalgamation. A small blower forces a gas generated by mixing ammonia and chloride of lime into the pulp just before it goes into the plate. It keeps the plates bright and in usual large tests has increased the gold saving from 8 to 20% above what had been caught without it.

Coarse material is furnished to jigs, then the jig tailings are reground by stamps or rolls for amalgamation, the tailings after amalgamation passing again to Wilfley tables. Each product of the four tables is kept separate and the working results of each separately noted. There is a Wilfley table on the same floor as the stamp mill and an hydraulic classifier. On the floor above is a Wetherill magnetic separator. This is an upright machine having endless belts working at right angles to one another in connection with a powerful electromagnet. The material or ore falls on the belt and is carried along under the magnet, which picks up whatever has magnetic attraction, the remaining product, carried by one of the belts, drops into a trough and is thus separated. A great range of metals that are not in their natural state magnetic become paramagnetic when roasted, e. g. iron and copper pyrites. As these have different degrees of attraction, the power of the magnet is graded accordingly, and further separation results, thus a certain power would attract roasted iron pyrites and another power roasted copper pyrites, whilst true magnetite is of course readily attracted and abstracted.

Besides these various devices and experimental processes for treating ore, outside at the back of the building are tons upon tons of iron, lead, and zinc slimes from Leadville. These have been treated and a successful separation made of the zinc from the lead and iron. The point made is, that the mill affords an opportunity for making tests on a commercial scale.

Whilst I was there a large consignment of ore came in from Mexico to be tested with a view to putting up a large mill in that country. An assay gives only a very approximate result, as we have said, but an actual test on a large scale at such a mill as this will show what actually will be done day by day at the mill to be erected and whether the erection of such a mill is warranted.

There were consignments of ore from all parts, amongst others we noticed three tons of gravel from the Cape Nome district, Alaska, just arrived, in which we saw the flat schist pebbles, characteristic of that region. This was for examination and testing.

In the basement of the building is a 40 H. P. steam engine, and a dynamo of 125 volts, 16 amperes, with 35 lamp capacity. The building is heated by the Webster steam heating system using the exhaust steam, which is also used in the drying of ores on the ground floor, where exhaust steam is drawn through 20 radiators and dryers. The building being on the level of the Platte River bottom, water is found in abundance just below the surface.

In Mr. Wood's assay office in Denver is a small counterpart of many of the various experimental devices of this larger establishment. These are for experiments on smaller lots of ore.

Denver is a good central location for plants of this kind on account of its numerous mining machinery establishments. Any mine owner after being satisfied with his results can at once order and duplicate any of the machinery required right in the city, which has advantages over a location distant from mines and mining machinery stores.

Much of the money lost in many unfortunate mining enterprises could have been saved and the mines in many cases put on a paying basis had thorough commercial tests been made before building the mills, which later had to shut down because they

were not adapted to the ore they were expected to treat. In these days there is no occasion for such failures, because it is an easy matter to obtain the necessary advice.

Balanced Shaking Screen.

The shaking screen, here illustrated, by reason of its construction, does not require any foundation, framework or bracing other than is needed to support the weight of the screen and resist the pull of the driving belt. The usual destructive shake or vibration common to all ordinary screens is in the case of this screen entirely prevented by a novel and very clever arrangement of the moving parts.

The forward and backward movement of the upper screen is perfectly counterbalanced by the reverse movement of the lower screen, and all of the thrust of the moving parts is completely absorbed in the heavy countershaft. No shake or vibration whatever is communicated to the structure upon which the screen is placed.

The screen frames are so placed on rocker arms that the screening surface always moves through a true arc. At each end of the stroke the material naturally raises slightly and is again forcibly caught by another portion of the screening surface. Great capacity and the most thorough separation is secured on any material whatever that is subject to screening process.

All bearings that require oiling are so far removed from the material that no oil or grease could possibly come in contact with the screened material.

Any material wet or dry that is subject to the process of screening can be rapidly and perfectly separated. Favorable materials such as sand, shale, fire clay, phosphate, cement, and coal, when dry are thoroughly screened at the rate of 15 to 20 tons per hour, and when damp at the rate of 10 to 15 tons per hour.

The dimensions are as follows: Length of upper and lower screens 14 feet; width 3 feet; height over all 26 inches; size of friction pulley 24" x 6"; speed of countershaft 250 R. P. M. Space required for screen complete on skids 18' x 4' 8".

The frame carrying the wire cloth or perforated metal is in removable panels for convenience in renewing the wire cloth and to provide for changes in the fineness of separation.

All who have seen the screens and observed their work, have recognized that The Aultman Company has

been successful in removing the objectionable features in shaking screens, also greatly increasing their capacity. They are now prepared to build this screen for the general trade, with either two or four separations, and to guarantee its satisfactory operation. Tests will be made on any material furnished and results submitted for consideration and comparison.

Inquiries are solicited from interested parties and will be given prompt attention. Descriptive catalogues are now ready for distribution.

An Excellent Work on Pumps.

The illustrated catalogue of steam pumps of the A. S. Cameron Steam Pump Works, East 23rd St., New York City deserves more than passing mention, being in reality more of a text book upon pumps than simply a catalogue. The illustrations are wonderfully clear and the directions and explanations very explicit. Each pump is described in detail and accompanying the description is a very complete and useful table, giving complete data for the various sizes of each style of pump made. The back of the book contains very useful data in regard to steam and water, also tables giving the areas of circles advancing by eighths; the pressure of water for different heights for every foot up to 260 feet; the friction loss in pounds pressure per square inch for pipes; capacity of pumps; heights to which pumps will elevate water, etc.

UNITED STATES COAL STATISTICS.

IN view of the very general interest which is now being taken in the coal resources of the United States and the probably very greatly increased export of coal to European countries, a few facts about the coal fields of the United States will be of general interest.

We are accustomed to hearing that our coal supplies are unlimited, and that our resources in this respect are unbounded, and a great deal of spread eagle talk has been indulged in along this line by those who are ignorant of the true state of the case.

To be sure we have an enormous area underlain by productive coal measures, but all of the coal fields are not equally productive nor do they all produce the highest grade of coal.

The coal areas of the United States are divided by the United States Geological Survey into two principal classes, anthracite and bituminous. Until very recently and still to a great extent, whenever anthracite was spoken of the coal fields of Eastern Pennsylvania were referred to, but it must not be forgotten that Colorado and New Mexico are now supplying a very good grade of anthracite to the Rocky Mountain region, and that small amounts of anthracite have been mined in Virginia for years and also a semi-anthracite in Arkansas, although the output from these latter two sources is always included in the reports of the bituminous product. The detailed division of the coal fields together with the estimated area of each, and the output of each in 1887 and during 1899, are given in the following table taken from Mr. E. W. Parker's report upon The Production of Coal in 1899, which forms a part of the 21st Annual Report of the United States Geological Survey.

An examination of this table shows how very nearly universally coal is distributed throughout the United States, while the production given shows the relative importance of the several sections at the present time. The coal areas as here tabulated would mean very much more if the thickness and quality of coal underlying each area could be stated, but our geological researches have not progressed far enough to allow this to be done as yet with any degree of fullness.

The output of anthracite including Colorado and New Mexico has increased from 39,548,255 short tons in 1887 to 60,514,201 short tons in 1899, or a little more than 50 per cent.

In commenting upon the relative importance of the various fields, as given above, Mr. Parker points out that the Western is the most extensive of the bituminous fields, having an area of nearly 100,000 square miles. In production, however, the fields of the Appalachian system are by far the most important, the yield from these fields, with an area about two-thirds of that of the Western, being over two-thirds of the total bituminous product of the United States. In 1899 the coal product of the Appalachian system was 129,872,259 short tons, an increase of 74,679,225 short tons, or 135.3 per cent. over 1887, and of 15,633,103 short tons, or 13.7 per cent. over 1898. Next in importance is the Central field, having an area of 47,750 square miles, and a production in 1899 of 33,181,247 short tons, about one-fourth of that of the Appalachian, and 17.2 per cent. of the total bituminous product. The Western field is third in producing importance, although first in size. Its product in 1899 was 15,320,393 short tons, about one-eighth of that of the Appalachian field and 8 per cent. of the total. The areas of the coal fields in the Rocky Mountain and Pacific coast fields have not been determined. The former, fourth in producing importance, has increased its output from 3,646,280 short tons in 1887 to 11,949,443 short tons in 1899. The Pacific coast fields produced in 1899, 2,277,741 short tons, 90 per cent. of which was from the state of Washington. The production of these five fields in 1887, 1898, and 1899, with the increases in 1899 as compared with the other two years, is shown in the following table.

From 1889 to 1899 the anthracite product increased $\frac{1}{2}$ and during 1899 the anthracite output exceeded the phenomenal yield of 1895 by 2 $\frac{1}{2}$ million tons.

Mr. Parker says in regard to this production:

The record made in 1899 is an important one. Not only did the production exceed all previous records, but it placed the United States at the head of the coal-producing countries of the world. The production in each of the last three years has been the largest up to that time. In 1897 the output reached for the first time a total of 200,000,000 short tons. The product in 1898 was 219,974,667 short tons, an increase of nearly 10 per cent. over

(c) Idaho only.

(e) Includes Alaska.

1897. The statistics for 1899 show an increase of 33,765,325 short tons, or 15.35 per cent. over 1898, and of 53,518,327 short tons, or 26.73 per cent. over 1897. Comparing the product in 1899 with some of the earlier years of our history, a still more remarkable advance is shown. In 1889 the total production of coal was 141,229,613 short tons, showing an increase in ten years of 112,510,379 short tons, or nearly 80 per cent. In 1879 our

production amounted to only 66,452,960 short tons, compared with which the output in 1899 shows an increase of about 280 per cent., while in 30 years the production has increased about 700 per cent., the yield in 1899 being eight times that of 1869, one generation ago. In the same period the production of Great Britain has about doubled, that of Germany has been multiplied by 4, and that of France by 2.5. In 1869 the coal product of Great Britain was nearly four times that of the United States, and that of Germany exceeded ours by about 20 per cent.

One of the interesting features of the history of coal production in the United States in the past three years is that the operators were prepared by the preceding years of depression to meet the demands made upon them by the period of prosperity through which the country has been passing. During the four or five years of "hard times" coal operators were contending with

Pacific Coast	174,698	8.3	1,423,433	166.6		

steadily declining prices, brought about by a continued overproduction and a keen competition for a market for the output. To meet these conditions, methods were adopted wherever possible for cheapening the cost of production by the installation of coal-cutting machines, mechanical haulage, etc., so that when the extraordinary demands of the past two years developed, many operators were able to expand their production 25 or 50 per cent. without materially increasing the lengths of their pay rolls.

Another feature worthy of note, which is shown in the statistics for 1899, is the advance in the average price per ton and a consequent increase in the value of the product proportionately greater than the increase in product. This is the first time in a period of twelve years when there has been an advance in the general average price. The improvement in the price of coal, however, was not as marked as that shown in many other commodities. Much of the coal marketed in 1899 was sold on contracts made the preceding year, and it was not until the latter part of the year that the operators began to reap actual benefits from the improved conditions.

SECOND-HAND MINING MACHINERY.

MINE owners, manufacturers or dealers, having second-hand mining machinery for sale, will find the Second-Hand Machinery Dept. started in the advertising pages of this issue, the best medium through which to secure purchasers.

Special rates of \$2.00 per inch per insertion have been adopted for second-hand machinery advertisements.

Mr. Carl R. Ickis formerly manager of the Denver Fire Clay Co., died in Denver, Colo., Tuesday, August 7th, 1900, at the age of 31 years.

Book Review.

ANNUAL REPORT OF THE DIRECTOR OF THE MINT, 1899. Washington, D. C.

REPORT OF THE EXECUTIVE COMMITTEE OF THE ANGLO-AMERICAN CLUB OF FREIBERG, SAXONY

BULLETIN OF THE SOCIÉTÉ SCIENTIFIQUE INDUSTRIELLE DE MARSEILLE published at Marseille, France.

ANNUAL REPORTS OF THE TREASURY DEPARTMENT FOR 1899. Production of gold and silver in the United States.

JOURNAL OF THE IRON AND STEEL INSTITUTE, 1900, No. 1, 517 pages edited by Bennet H. Brough, Secretary, 28 Victoria St., London, Eng.

SOME SILVER BEARING VEINS OF MEXICO, pamphlet, 16 pages, by Edward Halse. A paper read before the English Institution of Mining Engineers.

UNITED STATES TREASURY DEPARTMENT, CIRCULAR No. 113, Washington, D. C. Information respecting United States bonds, paper currency, coin, production of precious metals, etc., July, 1900.

JOURNAL OF THE CANADIAN MINING INSTITUTE FOR 1900, edited by the Secretary, B. T. A. Bell, Ottawa, Can. 268 pages, illustrated. The report contains 18 papers and in addition a detailed account of the meeting of the Institute together with the list of members.

JOURNAL OF THE SOCIETY OF ARTS, JULY 20TH TO AUGUST 3RD. This Journal is principally given up to the Cantor lectures which at present are being delivered by Mr. Bennet Brough, the well known English engineer, the subject being the Nature and Field of Metalliferous deposits.

THE CREDIT MAN, a journal published in St. Louis contains the following articles for September: Self Introductory; A Complaint Department for the Credit Men; What Has Been Done by the Credit Men's Associations? Foreign Corporations; Legal Status of Commercial Travelers; Increase of Failures; Three Cases of Special Interest to Bankers; Legal Problems for Credit Men; Legal Miscellany; Credit Men's Directory.

PAPERS READ BEFORE THE INTERNATIONAL CONGRESS OF MINING AND METALLURGY, Paris, France, and published by J. Thomas & Co., 12 Rue Germetet, Saint-Etienne, France.

GEOLOGICAL SURVEY OF ALABAMA, BULLETIN No. 6, PRELIMINARY REPORT OF THE CLAYS OF ALABAMA, Eugene A. Smith, State

Geologist, 219 pages not illustrated. This report is the result of the investigations by Dr. Heinrich Ries whose studies have been confined to the northern half of Alabama and to only one or two formations. The report shows that the clay resources of Alabama include every variety ranging from the best of China clays downward. The report is divided into three parts. Part 1 includes a general discussion of clays together with their methods of mining and preparation. Part 2 is a discussion of the geological relations of the clays of Alabama by Dr. Smith. Part 3 is the preliminary report of the physical and chemical properties of the Alabama clays by Dr. Ries. This report is a very interesting addition to the rapidly growing literature of clays. Its typography is not up to the standard which has been set in most of the other states, but this is possibly due to lack of appropriation and to no fault of the author or of the State Geologist.

VOLUME 7, PART 1, GEOLOGICAL SURVEY OF MICHIGAN, Alfred C. Lane, State Geologist. A geological report on Monroe County, by W. H. Sherzer, 17 plates, 3 colored maps, 240 pages. The scope of the book is best shown by the following chapter headings: Geographical and Historical Introduction; Devonian and Quaternary; Silurian Formations Quarries; Physical Geography; The Glacial Epoch in Southeastern Michigan; Soils and Subsoils; Economic Products; Minerals of Monroe County; Fossils of Monroe County. The typographical appearance of the book is excellent and the illustrations, maps, etc., very well shown. Some of the valuable results of Prof. Sherzer's work are the description of the considerable thickness and extent of the Sylvania glass-sand, a work of great value to a state so exceptionally well situated for glass manufacture as Michigan; the description of the deposits of high grade limestone and strontianite, both of which may be important factors in beet-sugar manufacture, while the former is also in great demand for the manufacture of soda ash; and the determination of the limited extent and economic value of the oil and gas. The professional geologist will appreciate the light thrown on the Helderberg question, and on the detailed history of the Great Lakes.

Personals.

The Howe Mfg. Co., has recently been formed with headquarters in Scranton, Pa., to handle the Howe Steam Dryer which rapidly and effectually dries sand and small coal. The officers of this company are President, A. O. Blackington; Vice President, C. W. Tenbroeck; Treasurer and Secretary, A. G. Thomason.

The Kenyon Ventilating & Force Fan Co. has been formed to handle a ventilating fan invented and recently patented by Mr. C. P. Kenyon of Scranton, Pa. The headquarters of this company are 603 Connell Bldg., Scranton Pa., and its officers are as follows: President, Alfred Harvey; Secretary and Treasurer, B. E. Kingsley; Directors, Alfred Harvey, C. D. Sanderson, B. E. Kingsley, R. F. Fox, C. P. Kenyon.

A number of changes have recently been announced by the Pennsylvania Coal Co., affecting both the Coal Co., and the Erie & Wyoming Railroad. Heretofore the mining and breaker departments have been separate, but these have now been combined under a number of district superintendents, each superintendent having direct charge of all the company's interest inside and outside. This new arrangement goes into effect about October 1st and the gentlemen in charge of the several departments will be as follows: George B. Smith, third vice-president; S. Brinckerhoff Thorne, comptroller; Sidney Williams, general superintendent; Andrew Bryden, consulting superintendent of mining; Alexander Bryden, mining engineer. The district superintendents have not yet been named.

Michigan College of Mines.

The purpose of the Michigan College of Mines, located at Houghton, Mich., is to train men to fill positions of usefulness in connection with the development of mining interests and the conduct of mining operations. It aims to train its students not for any particular kind of mining nor for any single operation, but rather to apply the principles of the great basal sciences of mathematics, physics, chemistry, and geology to the specific problems which may happen to confront them in their subsequent work. It endeavors to train not craftsmen but engineers. The College embraces departments of Mathematics and Physics, Chemistry and Metallurgy, Geology and Mineralogy, Mechanical and Electrical Engineering and Civil and Mining Engineering. It is obvious that mining engineering is a very broad field covering a wide extent of knowledge and methods. The range is so wide that no student can hope to cover thoroughly all of its departments in the ordinary college course. It was to meet these conditions that the elective system was put into operation, so that while a student is required to take the fundamental work necessary for all engineering, he is permitted to devote the greater part of his time to the lines for which he is best adapted.

CORRESPONDENCE.

This Department is intended for the use of those who wish to express their views, or ask or answer questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The editor is not responsible for views expressed by correspondents in this Department.

Correspondence should be in as simple language, and as free from technical terms and formulas as possible, consistent with clear solution.

Questions on subjects not directly connected with mining will not be published.

Relative Values of Products of Mining and Agriculture.

Editor Mines and Minerals:

SIR:—The articles which appear in MINES AND MINERALS are always of a high standard of excellence, combining the great qualities accuracy, clearness, minuteness of detail with that of being interesting. As I am continually on the move I find the Bound Volumes of MINES AND MINERALS too large and heavy to pack around, so I cut out all the articles which are of especial interest to me, number and index them and put them with other useful mining information and have them bound together, thus obtaining a handy reference book on a large variety of mining subjects, all in a nutshell so to speak.

I have always taken much interest in your paper and have noticed that you go a long way out of your way to oblige your subscribers with information, and I would like to ask, what was the value in the United States for any recent year of the total product gained by mining in comparison with that gained by farming (including stock raising), the products not to include manufactured stuff. I think the figures of the oil industry ought to go separate from mining proper. The same figures of Great Britain's product would also be interesting.

Yours truly,

Nelson, B. C.

A. P. BLANDY.

The value of the mineral production in the United States during 1899 has not yet been finally reported by the government in Washington, but advance reports indicate that it will be about \$1,000,000,000.

The advance bulletins of the Department of Agriculture give the following as the value of the farm products:

Buckwheat	6,183,675		
Oats	198,167,975		
Barley	29,594,254		
Hay	411,926,187		
Wheat	319,145,259	Milk Cows	514,812,106
Corn	629,210,110	Sheep	122,665,918
Rye	12,214,118	Horses	603,969,442
White Potatoes	89,328,832	Mules	111,717,092
Total	1,696,579,410	Other Cattle	689,486,250
			2,042,650,813

Miscellaneous Queries.

Editor Mines and Minerals:

SIR:—(1) What quantity of water per hour will be discharged by a pump 14 inches diameter, 30 inches stroke, running at a speed of 90 feet per minute? (2) An isolated coal field contains 100 acres, the seam is $4\frac{1}{2}$ feet thick, the specific gravity of the coal is 1.3; Assuming that 95 per cent. of the coal is recovered, how many short tons of coal will be produced from this coal field? (3) In what respect does the atmospheric pressure affect a siphon or a pump? (4) Where is the proper place to take a reading of the water gauge in a mine airway, and what precautions are necessary to procure a correct reading of the same? (5) In opening up a new coal field what conditions would determine the method of working the seam, whether the pillar-and-stall, or longwall, or room-and-chamber method should be used? (6) Give in brief your ideas in relation to the location and ventilation of mine stables.

Yours truly,

SUBSCRIBER.

1. The number of gallons of water (G) discharged per hour by a pump 14 inches diameter, 30 inches stroke, running at a speed of 90 feet per minute may be calculated by the formula,

$$G = 1.96 S d^2 = 1.96 \times 90 \times 14^2 = 34,574 \text{ gal. per hr.}$$

2. In a coal field containing 100 acres, 95 per cent. of the coal being recovered, we estimate upon 95 acres instead of 100. The weight of the coal in short tons (1 ton = 2,000 pounds) produced will then be,

$$W = \frac{43,560 \times 95 \times 4\frac{1}{2} \times 62.5 \times 1.3}{2,000} = 756,500 \text{ tons.}$$

An acre = 43,560 sq. ft.; 1 cubic foot of water = 62.5 lb.

3. The pressure of the atmosphere determines the vertical height a pump or a siphon will draw, since it is the pressure of the atmosphere that forces the water up the suction pipe. If we

denote the pressure of the atmosphere, in pounds per square inch, by p , we have for the theoretical height (H) the pump or siphon will draw, $H = \frac{p}{.434}$. The actual height in practice would be

about two-thirds of the theoretical height. (See article "Pressure—How Measured," page 331 of the February, 1900, issue of MINES AND MINERALS.)

4. A water-gauge reading should be taken at any air-tight door or brattice between the main intake and return airways, at a point close to the foot of the downcast shaft, or at the mouth of any split which it is desired to measure. The precautions necessary to be observed are that the door or brattice be air-tight; that the mouth of the gauge be protected from the direct force of the air current; that the gauge be vertical, and its reading carefully taken. (See answer to Ques. 30, 1900, page 273 of the January issue of MINES AND MINERALS.)

5. The conditions which determine the method to be employed in working any given coal field are briefly as follows: (a) Depth of the seam below the surface; (b) character of the strata forming the roof or floor of the coal seam; (c) character of the coal; (d) inclination and thickness of the seam; (e) presence of gas in the coal or in contiguous strata. (See article "Systems of Working Coal," pages 245 and 292 of the January and February issues of MINES AND MINERALS, 1899.)

6. Mine stables should be located at a point as convenient to the working face as possible, but where the mules can be rescued quickly in case of accident. The stables should be ventilated by a fresh-air split, which should be returned directly to the upcast; they should be well drained, and furnished with a good supply of pure water. The location of the stables should be such as to permit of easy access at all times, to remove refuse and supply the daily feed, etc. (See answer to Ques. 562, page 409 of the April, 1900, issue of MINES AND MINERALS.)

Arizona Notes.

Editor Mines and Minerals:

SIR:—In my last letter I partially promised something of especial interest to machinery men and also something of interest to investors in mining property. Things are shaping up nicely in this section for two or three good plants in the near future in the line of concentration, and cyanide plants. New discoveries, and good ore bodies being opened up nearly every week. We have not the railroads here that you have in the East. Two trunk lines east and west and one north and south with some small branches built and owned by mining companies constitute our transportation facilities. But men familiar with mining are not deterred by that, as is proven by the Rosborough copper property, about 90 miles from a railroad. Colorado people who know a good thing when they see it have fastened it, shipped in a hoist and are going at it in Colorado style. Business is their motto, and developments will result in this case in a mine. On Wallajai Mountain, Chas. Metcalfe and partner have a very promising group of claims. The Great Eastern claim on which the principal work is being done, is an immense ledge of what is termed low grade ore and is a fine concentrating proposition. The group has been just incorporated under the name of the Great Eastern Mining Co. Our warm weather is about passed and another month will see a general move in mining all over this country. The new smelter at Needles on the California side of the Colorado river will shortly blow in, and that will give a good many of the miners that can't stand transportation charges on a long haul a chance to have their ore treated. The inquiries for mining property are on the increase and come from all directions, and are indications of the interest that is being manifested in the business. I look for considerable activity during the balance of 1900.

In the last few years great strides have been made in perfecting mining machinery, and especially machines for the saving of precious minerals; but the writer has lately seen an ore concentrator which appears to have reached nearer perfection in the saving of values than any other concentrator ever before seen by him. The machine spoken of is the New Standard Concentrator made by the New Standard Concentrator Company, of Los Angeles, Cal.

In designing this machine the inventor has used the well-known bump principle to produce the separation, but has added new features and new principles, which have so perfected this class of machines that he has really established a "new standard" in the treatment of concentrating ores. He has provided means for imparting to the table a most perfect settling and separating motion, and at the same time he has given to the table the greatest possible range of adjustment to suit the different classes of ores. Very little power is required to operate this machine—about one-fourth horsepower, which is surprisingly little when the quantity of material treated is taken into consideration. The

amount of material treated per 24 hours will range from 15 to 30 tons, depending upon the percentage of heavy minerals in the ore.

One of the important features of the machine is the perfect separating surface of the table. This surface, while allowing of the rapid working of the ores, and rapid discharge of gangue, prevents the loss of any mineral by settling it below the action of the strong water currents until it is brought to the point of final cleaning. I have seen cleaner work and higher savings made on this machine than any concentrator I ever saw before, and it is only a question of a short time before this machine will supersede other ore concentrators on the market, as the mine owner of the present day must increase his profits by saving values from the gangue or tailings, which have hitherto been allowed to run away into the tailing pond.

Signal, Arizona, Sept. 3, 1900.

W. A. MENSCH.

Mensuration.

Editor Mines and Minerals:

SIR:—The following is an answer to Mr. I. C. Harrington's mensuration problem in the September issue of MINES AND MINERALS:

If a board is 12 ft. long and 12 inches wide at the big end and tapers from both sides to a point, I would like to know where it should be sawed across so as to have an equal amount of timber in each end.

Let x = the distance from the pointed end to the point at which the board should be sawed.

The area of the board = $\frac{12}{2}$ sq. ft. = 6 ft.

The area of half the board = 3 sq. ft.

The length of the saw cut = $\frac{x}{12}$.

and the area of the triangular portion = $\frac{x \times x}{2 \times 12} = \frac{x^2}{24}$

$\therefore \frac{x^2}{24} = 3$ and $x^2 = 72$.

$\therefore x = 6\sqrt{2} = 8.49$ feet.

Therefore the board would have to be sawed 8.49 feet from the pointed end.

Yours, etc.,

3 Kelso Road, Leeds, England.

J. E. TIFFANY, B. Sc.

Let x = length of the cut, y the distance from the base to the cut.

Superficial area whole board = 6 square feet. Whole area = $6 = y + xy = y(1+x)$, or $y = \frac{6}{1+x}$. (1)

By proportion $12 - \frac{x}{y} = \frac{1}{12}$ or $12x = 12 - y$
or $y = 12 - 12x = 12(1-x)$. (2)

Substitute value of y in (1) we have $12(1-x) = \frac{6}{1+x}$ or $1 - x^2 = .5$;
or $x^2 = .5$.

$\therefore x = .7071$ ft. or practically $8\frac{1}{8}$ inches, and

$y = \frac{6}{1.7071} = 3.515$ or 3 ft. $6\frac{1}{8}$ inches.

$\therefore$ Saw the board 8 ft. $5\frac{1}{8}$ inches from the point A.

Yours, etc.,

Salt Lake City, U.

H. S. J.

Centrifugal Ventilators.

Editor Mines and Minerals:

SIR:—Mr. Markmann under the heading "Centrifugal Ventilators," in the Correspondence Columns of your August issue, further criticised my article upon the designing of these machines. Having shown that in any circulation the work of compression due to the action of the ventilating pressure is identical with the effective work Qp performed by the motor in maintaining circulation, he objects to our deductions therefrom; viz., that this identity serves to verify our results. In formula 2 we equated Qp with the work expressed in terms of the motor (formula 1), and are hence justified in looking for equivalent results in formulas 1 and 3. However, the writer's original statement in this regard (page 55, MINES AND MINERALS, September, 1899) referred to the lack of identity between formula 1 expressing the work of the motor in terms of the motor, and formula 3 expressing the work of compression. It is these expressions of work that though giving equivalent results through all the various changes of volume and pressure, are still unidentical; and it is through the equivalency of these results that we have claimed that the latter verifies the former.

In another paragraph the writer of the criticism admits that the compressive formula may be written $Q_1 p_1 \log \text{nat } \frac{p_1}{p_0}$, in place

of $Q_0 p_0 \log \text{nat } \frac{p_1}{p_0}$, but claims it is the latter that reduces to the form $u_c = Qp$, whereas either of these forms will reduce to the same general equation expressing the work of compression as being approximately equal to Qp , since $\frac{p_1}{p_0}$ under the hypothesis becomes approximately equal to 1, giving finally $u_c = Qp$ approximately.

In the next paragraph the obviously erroneous statement is made that "The force applied to the resistance must be proportioned to the latter." Why? For the same velocity or time, this would be correct. Two men will raise double the load raised by one man, in the same time; but we may employ ten men or twenty men or any force at hand to raise the same load. Most certainly the centrifugal force developed in the fan is not proportional to the resistance, for as the mine resistance is increased in development, the quantity of air in circulation is decreased at the same speed of the fan developing the same centrifugal force. Such a statement is careless in the extreme, and this error renders void the statement, in the same paragraph, that the

centrifugal force $\frac{W V_p^2}{g - \rho}$ being proportional to V_p^2 (velocity of the center of gravity of one compartment of the fan), or n^2 (speed of rotation of the fan), Q is therefore proportional to n . The relation of the speed of rotation n to the quantity or yield Q is not to be determined in so simple a manner, but must be referred to the basis of work performed.

The next point considered is our method of obtaining the expression for the work of the fan *per unit of time*, and the statement is made that we have in all of our papers up to date used

the expression $U = mf \times \frac{f}{2}$ for "the work of the constant force mf for each second." As a matter of fact we have always based our calculations upon the work the fan will perform in a minute, instead of a second of time, finding the former unit more convenient than the latter, since the circulation is given in cubic feet per minute. But emphasis is laid upon the fact that we have called this the work of acceleration for each unit of time, and attention is drawn to the fact that work of acceleration is different for every unit of time, and that the expression referred to above expresses the work for the first second of acceleration only, which is true. But refer to our hypothesis that the work of the fan is a work performed upon a fixed quantity of air Q , (cubic feet per minute); such quantity of air being brought from a state of rest to a state of motion. The limiting conditions are rest and motion; the work is regularly performed upon a quantity of air Q , and is accomplished in exactly a unit of time. Under this hypothesis we are not concerned with what the work would be in the next minute, or in any succeeding minute, the expression for this work of acceleration being complete in the first second. Under this hypothesis it is a uniform work performed each minute upon a fixed quantity of air. The question might properly be asked, "Is the acceleration f the same as the velocity v , in the airway?" Certainly not. It would be were the centrifugal

force F equal to the resistance $\frac{pa}{K}$, but it is an unwarranted assumption to make it so. The force applied to move a mass is not necessarily equal to the mass. The force applied to the end of a lever may be greater or less than the weight it moves, and only when the distances through which the respective movements take place are equal can the force be equal to the resistance. In the same way the acceleration f due to the centrifugal force F is only equal to v when the force F is equal to the total resistance $\frac{pa}{K}$. We refer to this again below.

The first velocity v in this case is zero, in the expression found in Ganot's "Elements de Physique" $U = \frac{1}{2} m (v_1^2 - v^2)$,

which becomes $U = \frac{1}{2} m v_1^2$, and we were right in saying "The change of the square of the velocity for a unit of time would be the square of the acceleration," in this case. The words in which Dr. Atkinson, in his translation of Ganot, paraphrases this formula are correct in our humble opinion. "The change of the square of the velocity" can only mean the difference of the squares of the velocities.

The statement that $\frac{pa}{K}$ is not the resistance does not prove anything. If pa is the effective or mine resistance and K the coefficient of efficiency of the motor, we fail to see why $\frac{pa}{K}$ is not the correct expression for the total resistance, or the resistance of the mine and the motor together.

To what does the term efficiency refer in this case? Mr. Markmann compares the efficiency given in our example ($K = .8392$) with other published efficiencies of ventilating motors, stating that they rarely exceed 70%. The term efficiency is a broad term. In the usual sense in which it is used in reference to fans, it refers to the percentage of the work shown by the engine card that becomes effective upon the air in the airway. The engine card work includes not only the work absorbed in running the engine, but also that of revolving the fan. The writer has frequently drawn attention to the fact that both of these works should be eliminated in estimating efficiency as in this formula. The question is, What percentage of theoretical power does this or that type of construction make effective? In this calculation allowance might preferably be made for the mechanical revolution of the fan, but never for that of the engine, as the latter is not a part of the fan. To make this clear we will refer to a test of a Capell fan, made at Scalp Level, Pa., as recorded on page 318, MINES AND MINERALS, February, 1898, in which an efficiency of 71% is shown at a speed of 200 revolutions per minute. The indicated horsepower of the engine was 204 h. p. Thurston in his Manual of the Steam Engine, page 556, Vol. I, states that the percentage of the power of an engine running under full load that is absorbed by itself varies from 5 to 10 per cent., according to the state of lubrication, etc. This latter is never too good in the case of a fan engine, and we are safe in assuming that of the 204 horsepower, in the Scalp Level test, 20 horsepower was consumed in running the engine and perhaps 16 in running the fan, exclusive of the air, leaving 168 as the actual indicated horsepower applied to the generation of an air current. The horsepower of this current as measured in the fan drift was 145 h. p., thus showing an efficiency, on a formula basis, of 86.3 per cent.

The assertion that "The work of the fan is not a work of acceleration, because it is work against resistance" will not find a shadow of support in the established laws of mechanics. Referring to the illustrations of a ship sailing or a train moving at a uniform speed, quoted from Ganot, where they are used as illustrations of force producing uniform motion against resistance, we would ask, Is there anything in the quotation that supports the deductions drawn from them? Was there no resistance present when the ship or train was starting from rest, and attaining a uniform velocity? The quotation speaks of the force as producing a uniform velocity against resistance, but does not even vaguely hint that acceleration cannot take place against resistance. The study of Attwood's gravity machine will help to answer the question whether or not acceleration takes place against resistance, (page 522 MINES AND MINERALS, June, 1900). In the Attwood machine two equal weights are suspended from the opposite ends of a cord that passes over a frictionless pulley. An additional weight representing the accelerating force is now added to one of the equal weights, and imparts motion to the entire system. This is an illustration of acceleration against resistance, and furnishes an interesting study. For example, if the additional weight were allowed to drop freely under the influence of gravity, its acceleration would be g , but when resisted by the other weights and imparting motion to a mass greater than itself, the acceleration is no longer g but f . In the one case the accelerating force is equal to the weight of the body accelerated, in the other case it is not; but always the ratio of the accelerations is equal to the ratio of the masses accelerated. For example, the acceleration due to gravity is g , that due to the force F is f . Gravity acting upon a mass m produces the force W which we call weight; and always $\frac{F}{W} = \frac{f}{g}$. And since $W = mg$, $F = mf$. Only when $F = W$ does $f = g$. This is the case when a body falls freely under the influence of gravity, or a mass is moved by a force equal to its own weight. But when the accelerating force is not equal to the weight of the mass accelerated, the acceleration must be calculated as above. This little study teaches that *Acceleration against resistance bears the same ratio to the acceleration of a falling body (in vacuo) as the moving force bears to the resistance.* Applying this to our present case, the accelerating force is the centrifugal force F developed in the fan. The total pressure or resistance $\frac{pa}{K}$ represents the weight of the entire mass accelerated.

The work performed by the motor is the work performed each minute of time, in bringing a fixed quantity of air (cubic feet per minute) from a state of rest in the atmosphere to a uniform velocity in the airway. The acceleration f is not v . The former is a function of the centrifugal force developed in the fan, while the latter is a function of the resistance to the circulation. The work of the centrifugal force, however, is equal to the work of the resistances; and we write

$$60 F \frac{f}{2} = Q p.$$

Yours truly,
J. T. BEARD.

Scranton, Pa., August 11, 1900.

PRIZE CONTEST.

Prizes Given for the Best Answers to Questions Relating to Mining.

For the best answer to each of the following questions, the value of \$1 in any of the books in our book catalogue, or six months' subscription to MINES AND MINERALS.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue, or three months' subscription to MINES AND MINERALS.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to MINES AND MINERALS.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition Contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed to us not later than one month after publication of the question.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Ninth—In awarding prizes, other things being equal, a carefully written and arranged answer will be given the preference.

Competition Questions for October.

QUES. 620.—*Principle of the Safety Lamp.*—Explain clearly and simply the principle of the safety lamp, or tell in a few plain words what prevents the flame of the gases burning within the lamp from passing through the apertures of the wire gauze.

QUES. 621.—*Measurement of Water Flowing in a Ditch or Flume.* The weir opening of a certain flume is exactly 72 inches in width, and the depth of water flowing over the weir is 5½ inches. Calculate the number of gallons of water flowing over the weir per minute. Desiring to check the measurement of the flow in this flume, a little piece of board was floated upon the surface of the water in the flume, and the time observed that it took to pass between two points 50 feet apart. The observed time was 36 seconds. The full width of the flume in the clear is 80 inches, and the depth of the water 8 inches. Show how closely this latter observation checks the first calculation.

QUES. 622.—*Size of Pump.*—Calculate the size of a direct acting pump that will discharge 1,600 gallons of water per minute from a sump at the bottom of a shaft 300 feet deep, assuming the steam cylinder pressure to be 80 pounds per square inch.

QUES. 623.—*Force Required to Open a Mine Door.*—Calculate the force required to pull open a mine door at the shaft bottom, between the main intake and return entries of a mine, the water-gauge reading at the door being 3 inches. The size of the door is 5 ft. × 6 ft., and the position of the handle is 5½ feet from the axis of the hinges. The door is assumed to fit snugly and to be practically air-tight.

QUES. 624.—*Mine Resistance, How Affected by Splitting.*—When the air current passing in a mine is divided into two or more equal splits, is the resistance of the mine thereby diminished or increased, or does it remain the same after the splitting as before, assuming the power upon the air is constant?

QUES. 625.—*To Determine the Dip of a Seam by Means of Three Bore Holes.*—In order to determine the amount and the direction of the dip of a certain coal seam, three holes were sunk to the seam as follows: Hole A is N 49° 20' E, 1,500 yards from hole B; and hole B is S 5° 50' E, 230 yards from hole C. The surface elevations above datum, and the depth of the holes are respectively as follows: A, elevation 980 ft., depth 300 ft., B, elevation 650 ft., depth 270 ft., C, elevation 1,090 ft., depth 740 ft. Determine the depth of a shaft located at a point 400 ft. S 15° W of hole A, where the surface elevation is 710 ft.; also determine the course or bearing of a slant road in this seam having a grade of 1 in 10, dipping in a southerly direction.

QUES. 626.—*Acceleration Against Resistance.*—Can acceleration take place against resistance, and if so, how is acceleration to be determined? Does the tractive force of an engine accelerate the motion of a train until a uniform grade is attained, and why does it not continue to accelerate always, or what is the limit to the acceleration in such a case?

QUES. 627.—*Arrangement of Shaft Bottom.*—Describe the arrangement of the tracks, manway, pumps, etc., at the bottom of a shaft 250 feet deep, and making 1,200 gallons per hour, the output of the shaft being 1,000 tons per day of 10 hours and all of the pumping to be done in four hours, or between shifts, morning and evening. Give the size of pump, size of shaft, and depth of sump, and length and grade of shaft bottom. Caging is to be done from both sides of the shaft, and arrangements must be made for cross-caging in case of unequal production.

Answers to Questions Which Appeared in the August and Previous Numbers and for Which Prizes Have Been Awarded.

QUES. 586.—The air in a certain mine is traveling in two splits, as follows: Split A, which is 6 ft. $\times$ 8 ft. and 10,000 feet long, is passing 40,000 cubic feet of air per minute, split B, which is 8 ft. $\times$ 12 ft. and 14,000 feet long, is passing 80,000 cubic feet per minute. We cannot increase the power of the ventilator; but we desire more air in split B, especially. Splits A and B start from the bottom of the downcast shaft. The shafts are each shallow and have a large area, so that their resistances may be ignored. We find, after careful consideration, that it is possible to again split the air traveling in B, at a point 2,000 feet inbye from the foot of the downcast, thereby forming two secondary splits as follows: Split c, 8 ft. $\times$ 12 ft., 4,000 feet long; split d, 8 ft. $\times$ 12 ft., 6,000 feet long; while split B would, then, be 8 ft. $\times$ 12 ft., and 4,000 feet long, including its return. Before making this change, however, we would like to be able to tell exactly what benefit would be derived by so doing; since some work is necessary in the way of erection of doors, overcasts, etc., which entails expense. With the same power of ventilator, can you tell me what quantity of air will pass in each split without the use of any regulators?

ANS.—Let us, first of all, find the amount of work the ventilator must perform to pass 40,000 cubic feet of air per minute through split A, and 80,000 cubic feet through split B. The pressure is $p = \frac{.00000001 \times 280,000 \times 833\frac{1}{3}}{48} = 40.51$ lb. per sq. ft. Then, as the pressure per square foot is the same for both splits, the total work is $U = p q = (40,000 + 80,000) \times 40.51 = 4,861,125$ foot-pounds.

Let v_1, a_1, s_1, p_1 , etc., v_2, a_2, s_2, p_2 , etc., v_3, a_3, s_3, p_3 , etc., v_4, a_4, s_4, p_4 , etc., represent the velocity, sectional area, rubbing surface, pressure per square foot, etc., for A, B, c and d splits respectively.

Then,
 $a_1 = 6 \times 8 = 48$ sq. ft., and $s_1 = 2(6 + 8) \times 10,000 = 280,000$ sq. ft.
 $a_2 = 8 \times 12 = 96$ sq. ft., and $s_2 = 2(8 + 12) \times 4,000 = 160,000$ sq. ft.
 $a_3 = 8 \times 12 = 96$ sq. ft., and $s_3 = 2(8 + 12) \times 4,000 = 160,000$ sq. ft.
 $a_4 = 8 \times 12 = 96$ sq. ft., and $s_4 = 2(8 + 12) \times 6,000 = 240,000$ sq. ft.

Now, $p = \frac{k s v^2}{a}$, but $p_1 = p_2 + p_3$; hence, $\frac{k s_1 v_1^2}{a_1} = \frac{k s_2 v_2^2}{a_2} + \frac{k s_3 v_3^2}{a_3}$, or $\frac{s_1 v_1^2}{a_1} = \frac{s_2 v_2^2}{a_2} + \frac{s_3 v_3^2}{a_3}$, and substituting known values, we have, $\frac{28 v_1^2}{48} = \frac{16 v_2^2}{96} + \frac{16 v_3^2}{96}$, or by reduction $3.5 v_1^2 = v_2^2 + v_3^2$.

Now, since the areas are equal, in this case, $v_2 = v_3 + v_4$. But, v_3 and v_4 vary inversely as the square roots of the lengths of the airways, which are as 4:6. Hence, the relative velocities in these splits are as follows: $v_3 = \sqrt{6} = 2.4495$ ft.; $v_4 = \sqrt{4} = 2$ ft. and $v_2 = 2.4495 + 2 = 4.4495$ ft. per min. Then $3.5 v_1^2 = 4.4495^2 + 6 = 25.798$; and $v_1 = \sqrt{\frac{25.798}{3.5}} = 2.715$.

The power for each split is proportional to $s v^2$. Hence, the relative work absorbed by each split is as follows:

$$\begin{aligned} s_1 v_1^2 &= 28 \times 2.715^2 = 560,362 \text{ ft. lb.} \\ s_2 v_2^2 &= 16 \times 4.4495^2 = 1,409,452 \text{ ft. lb.} \\ s_3 v_3^2 &= 16 \times 2.4495^2 = 235,158 \text{ ft. lb.} \\ s_4 v_4^2 &= 24 \times 2^2 = 192,000 \text{ ft. lb.} \end{aligned}$$

Total relative work, 2,396,972 ft. lb.

We found, above, that the work performed by the ventilator is equal to 4,861,125 foot-pounds. Hence, the ratio of work is $\frac{4,861,125}{2,396,972} = 2.028$; and we have for the actual work absorbed in each respective split, as follows:

$$\begin{aligned} u_1 &= 2,028 \times 560,362 = 1,136,421 \text{ ft. lb.} \\ u_2 &= 2,028 \times 1,409,452 = 2,858,400 \text{ ft. lb.} \\ u_3 &= 2,028 \times 235,158 = 476,900 \text{ ft. lb.} \\ u_4 &= 2,028 \times 192 = 389,375 \text{ ft. lb.} \end{aligned}$$

Finally, $q = a \sqrt{\frac{u}{k s}}$; hence, we have for the quantity of air that will circulate in each split

$$q_1 = 48 \sqrt{\frac{1,136,421}{.00000001 \times 280,000}} = 35,539 \text{ cu. ft.}$$

$$q_2 = 96 \sqrt{\frac{2,858,400}{.00000001 \times 160,000}} = 116,484 \text{ cu. ft.}$$

$$q_3 = 96 \sqrt{\frac{476,898}{.00000001 \times 160,000}} = 64,127 \text{ cu. ft.}$$

$$q_4 = 96 \sqrt{\frac{389,384}{.00000001 \times 240,000}} = 52,359 \text{ cu. ft.}$$

Very truly yours,

ADOLPHE COOK, Cokeville, Pa.

[Owing to the importance of this question as a practical problem in the ventilation of mines; and on account of the difference in the methods of solution, we give below the answer which merits the second prize. Other answers were received making use of the term *moment of resistance*. They were, however, not as clear and reasonable.]

Second Prize.—

ANS.—Assuming a velocity of 1 in split B, the pressure will be found from the equation $p = \frac{k s v^2}{a}$ and taking .00000001 as the coefficient we have for forcing 96 cubic feet of air through split B, and its return a pressure $p = \frac{.00000001 \times 160,000 \times 1^2}{96} = .00001667$ pounds. The quantities in splits c and d will be inversely proportional to the square roots of their lengths, and eliminating the ciphers, we have for the relative quantity of air that will circulate in split c, $\frac{\sqrt{6} \times 96}{\sqrt{4} + \sqrt{6}} = 52.85$ cu. ft. The pressures for splits c and d being equal we need only find the pressure for c and it is $p = \frac{.00000001 \times 160,000 \times (52.85)^2}{96} = .0000505$ pound. This makes the pressure (p) for split B to circulate 96 cubic feet of air .00001667 + .0000505 = .00002172 pound. As we will have the same pressure for split A, the relative quantity of air in split A is found from the expression

$\sqrt{\frac{p a}{k s}} \times a$; and substituting values, we have, $\sqrt{\frac{.00002172 \times 48}{.00000001 \times 280,000}} \times 48 = 29.29$ cu. ft. This makes the total relative quantity $96 + 29.29 = 125.29$ cubic feet of air circulating in the mine under a pressure of .00002172 pound. The expression for the work performed is $u = q p$, and the work performed in circulating this quantity is therefore $125.29 \times .00002172 = .00272125$ foot-pounds.

The original pressure (p) required to circulate the given quantity is found from the expression $p = \frac{k s v^2}{a}$ and substituting the given values we have, $p = \frac{.00000001 \times 280,000 \times (4.4495)^2}{48} = 40.51$ pounds. For the available units of work we have $u = (80,000 + 40,000) \times 40.51 = 4,861,200$ foot-pounds. The quantity that will circulate in the mine after the splits are made, and with no regulators in use is therefore $\frac{4,861,200 \times 125.29}{.00272125} = 152,021 + \text{cu. ft.}$

The quantities that will now pass through splits A, B, c and d respectively is found as follows: for

$$\text{Split A} = \frac{29.29}{125.29} \times 152,021 = 35,539 \text{ cu. ft.}$$

$$\text{Split B} = 152,021 - 35,539 = 116,482 \text{ cu. ft.}$$

$$\text{Split c} = \frac{52.85}{96} \times 116,482 = 64,127 \text{ cu. ft.}$$

$$\text{Split d} = 116,482 - 64,127 = 52,355 \text{ cu. ft.}$$

Proof. $u = q p$ and taking the values for split A, velocity $= \frac{35,539}{48} = 740.4$ ft. per min. Then,

$$p = \frac{.00000001 \times 280,000 \times 740.4^2}{48} = 31.978 \text{ lb.}$$

and the units of work $u = 152,021 \times 31.978 = 4,861,200$ ft. lb.

JAMES RADFORD, Springfield, Ill.

[Another method of solution of the above example is the method by the *potential* which is simple and shorter than either of the two preceding methods. In splitting air-currents it is customary to consider the pressure per square foot or *unit pressure* (p) as the same for all the splits; its expression being $p = \frac{k s}{a^3} q^2$. It is evident, k being constant, q varies directly as the expression $a \sqrt{\frac{p}{k s}}$ which we call the *pressure potential*; and writing X_p for this

potential, we have for the pressure producing circulation in any split or airway, $p = \frac{q^2}{X_p} \times k$.

Solution.—First find the pressure potential for each split indicating the several splits by the subscript letters 1, 2, 3, 4; thus for

$$\text{split } A, X_1 = 48 \sqrt{\frac{48}{2(6+8) \times 10,000}} = .6285;$$

$$\text{split } B, X_2 = 96 \sqrt{\frac{96}{2(8+12) \times 4,000}} = 2.3515;$$

$$\text{split } c, X_3 = 96 \sqrt{\frac{96}{2(8+12) \times 4,000}} = 2.3515;$$

$$\text{split } d, X_4 = 96 \sqrt{\frac{96}{2(8+12) \times 6,000}} = 1.9200.$$

For constant pressure, or for all splits starting from the same point, as for example splits c and d , we have

$$\text{or, } \frac{q_3}{X_3} = \frac{q_4}{X_4} \therefore X_3 : X_4 :: q_3 : q_4.$$

Whence, $\frac{q_3}{X_3} = \frac{(q_3 + q_4)}{(X_3 + X_4)}$, and in general, indicating the sum of all the quantities in any number of splits starting from one point by Σ , we have, $\frac{q}{X_p} = \frac{\Sigma q}{\Sigma X_p}$. And always the pressure due to the splits is the square of this ratio, multiplied by the coefficient k , or $p = \left(\frac{\Sigma q}{\Sigma X_p}\right)^2 \times k$. From what precedes, we write for the relative pressures, remembering that $q_3 = q_3 + q_4$.

$$\text{Split } A, p_1 = \left(\frac{q_1}{X_1}\right)^2 = \frac{q_1^2}{.6285^2} = 2.532 q_1^2;$$

$$\text{split } B, p_2 = \left(\frac{q_2}{X_2}\right)^2 = \frac{q_2^2}{2.3515^2} = .1808 q_2^2;$$

$$\text{splits } c \text{ and } d, p_3 = \left(\frac{q_3}{X_3 + X_4}\right)^2 = \frac{q_3^2}{4.2715^2} = .0548 q_3^2.$$

$$\text{But } p_1 = p_2 + p_3 \text{ which gives the equation } 2.532 q_1^2 = (.1808 + .0548) q_2^2,$$

or,

$$q_2 = 3.2781 q_1,$$

and calling

$$Q = q_1 + q_2, \text{ we have}$$

$$Q = 4.2781 q_1,$$

or,

$$q_1 = .2338 Q.$$

Now since the power cannot be increased, the units of work Qp is the same before and after the change; hence,

$$120,000 \left(\frac{40,000}{X_1}\right)^2 = Q \left(\frac{q_1}{X_1}\right)^2$$

and writing for q_1 its value $.2338Q$, we have after reducing,

$$Q = \sqrt{\frac{120,000 \times 40,000^2}{.2338^2}} = 152,029 \text{ cu. ft.}$$

as the total quantity of air in circulation. Then the quantity circulating in each split is as follows:

$$\text{Split } A, q_1 = .2338 \times 152,029 = 35,539 \text{ cu. ft.};$$

$$\text{split } B, q_2 = 152,029 - 35,539 = 116,490 \text{ cu. ft.};$$

$$\text{split } c, q_3 = \frac{2.3515}{4.2715} \times 116,490 = 64,130 \text{ cu. ft.};$$

$$\text{split } d, q_4 = \frac{1.92}{4.2715} \times 116,490 = 52,360 \text{ cu. ft.}$$

—EDITOR.]

QUES. 604.—Preservation of Mine Timber.—What is the action of creosote in the preservation of mine timber? Describe also the manner in which timber is preserved by charring.

Ans.—The action of creosote upon wood may be described as follows:

(1) *A chemical action.*—It is a fact that acids are not truly antiseptic but they possess to a greater or less degree the power of coagulating albumen. It is this property that does more to preserve the timber than anything else. The tarry acid having effected the coagulation of the albumen of the wood sap, this coagulated albumen mixes with the naphthalene of the creosote which as soon as the temperature becomes sufficiently reduced is redeposited and forms along with the heavier, oily portion a solid magma within the pores and fibers of the wood.

(2) *A physical action* or choking up of the pores of the wood by the solid magma formed as described above. This prevents the absorption of moisture by the wood and arrests decay.

(3) *A physiological action.*—The antiseptic property of the creosote destroys the organic life in the wood and prevents the development of germs or fungi which are known to be destructive to timber.

By charring the ends and surface of timber you seal the pores of the wood and prevent moisture from creeping up and starting the germ life in the wood which would in a short time destroy the life of the wood. The carbon formed by the charring of the surface of the timber is indestructible.

HENRY LAMPARD, Montreal, Canada.

Second Prize.—ALEX. DIXON, Weir City, Kansas.

QUES. 605.—Cutting Mine Timber.—In what season of the year should mine timber be cut, and why? State all the reasons that you know for and against the cutting of mine timber at such time.

Ans.—The most favorable months for cutting mine timber are December, January, and February. During these months, there is comparatively little sap in the tree. If cut when sap is circulating through the tree, rapid decay of the timber ensues from the fermentation of the sap. If cut during these months, the timber is more readily seasoned by the drying out of what sap is present and seasoned timber will last fully one-quarter longer than green timber. Another argument in favor of cutting timber during these months is that it is much easier to secure workmen for the forest [and transportation to the mines is usually cheaper] during the winter months. [In temperate climates, the circulation of sap in forest timber has practically ceased toward the close of December, but starts again about the middle of February. The only argument in favor of cutting timber in the summer season is the employment thereby given to miners when they are idle.]

D. C. PHILLIPS, Hiteman, Iowa.

Second Prize.—FRANK CRAGGS, East Hedley Hope, Tow Law, Durham, England.

QUES. 606.—Gravity-Plane Haulage.—Calculate the size of rope required to lower an output of 1,000 tons per day of 10 hours, over an incline 300 yards long. The upper landing is 50 feet of vertical height above the tippie. Draw a sketch also showing the profile of the incline, from the tippie to the upper landing. Calculate the starting and stopping grades at the head and foot of the incline respectively, and the uniform grade of the incline. Assume a rolling friction of $\frac{1}{10}$ of the normal pressure upon the plane, and the weight and capacity of the mine cars as 1,500 and 2,200 pounds, respectively.

Ans.—Number of wagons lowered each trip, assuming a speed of 30 feet per second, or $\frac{300 \times 3}{30} = 30$ seconds or one-half minute

for each trip, and allowing also one-half minute for changing ropes, making the time for one round trip 1 minute; then,

$$\frac{1,000 \times 2,000}{10 \times 60 \times 2,200} = 1.515 \text{ cars per trip. Or, say 2 cars per trip,}$$

$$\text{the time per trip will be } \frac{10 \times 60 \times 2,200 \times 2}{1,000 \times 2,000} = 1.32 \text{ minutes,}$$

which gives $1.32 - .5 = .82$ minute for changing ropes.

To determine the size of rope required, we first find the general angle of inclination of the plane (a); thus, $\frac{50}{900} = .0555$

$= \sin a$; whence $a = 3^\circ 11'$ and $\cos a = .9984$. The tension or pull (T) on the rope is then the sum of the gravity pull and the friction pull due to the loaded trip and the rope. Thus,

$$T = (W + w) \left(\sin a + \frac{\cos a}{20} \right) = [2(1,500 + 2,200) + 900 \times .88]$$

$$\times \left[.0555 + \frac{.9984}{20} \right] = 863 \text{ pounds. Doubling this to provide}$$

against shock, and using a factor of safety of 10, we have for the breaking strain $\frac{863 \times 2 \times 10}{2,000} = 8.63$ tons. From the tables giving

the strength of wire ropes, we find this would require a $\frac{1}{2}$ -inch plough-steel rope having a breaking strain of 9 tons; but to provide for wear of rope, we will use a $\frac{3}{4}$ -inch steel rope weighing .41 pound per foot, and having a breaking strain of 13 tons.

In starting the trip from the bottom, where the track is practically level, the gravity pull of the rope and the friction pull of the entire system are the resisting forces. The gravity pull of rope is $900 \times .41 \times .0555 = 20.5$ pounds. The starting friction we estimate as double the rolling friction, or $\frac{1}{10}$ th of the weight of the entire moving load (2 loaded cars = 7,400 lb.; 2 empties = 3,000 lb.; 1 rope 369 lb.). Hence the entire resisting pull

$$\text{in starting is } 20.5 + \frac{7,400 + 3,000 + 369}{20} = \text{say } 559 \text{ pounds. This}$$

is equal to the gravity pull of the loaded trip (7,400 lb.) on the steep pitch. Hence, calling the angle of the steep pitch B , we have $\sin B = \frac{559}{7,400} = .07554$; or $B = 4^\circ 20'$.

After the load has started the resisting pull is

$$20.5 + \frac{7,400 + 3,000 + 369}{40} = \text{say } 290 \text{ pounds,}$$

while the gravity pull of the loaded trip remains constant (559 lb.).

Hence, to find the acceleration (f) of the system, we have

$$f = \frac{559 - 290}{559 + 290} \times 32.16 = 10.19 \text{ feet per second, and the length of the steep pitch is then, } \frac{v^2}{2f} = \frac{30^2}{2 \times 10.19} = 44.2 \text{ feet.}$$

The stopping grade at the foot of the incline will be a practical level of the same length as the starting grade at the top. Correcting for the uniform grade, we find its length is practically $900 - 2(44.2) = 811.6$ feet, and its rise $50 - 44.2 \times \sin 4^\circ 20' = 50 - 44.2 \times .0755 = 46.7$ feet. Then finally $\sin a = \frac{46.7}{811.6} = .05754$; or $a = 3^\circ 18'$, instead of $3^\circ 11'$ as before.

N. G. BOLLING, Greensburg, Penna.

Second Prize.—WILLIAM D. ROBERTS, Graceton, Penna.

QUES. 607. *Strike and Dip of Seams.*—Give a clear explanation of what you mean by the terms "strike" and "dip" in reference to inclined seams.

ANS.—*Strike.* Imagine a horizontal plane surface $ABCD$ intersected by the inclined plane $FGHI$ representing an inclined seam. The line of intersection ML of these two planes being a level line in the seam is a line of strike or the strike of the seam and its direction is measured by the angles $MO M$ or $SO L$ which it makes with a true north and south line (meridian). This angle is always a horizontal angle, lying in the plane of the horizon; thus, in the present case, the strike of the seam may be said to be $N 45^\circ E$, or $S 45^\circ W$.

Dip. At any point (O) of ML draw lines OP and OR at right angles to ML in the horizontal plane and in the plane of the seam, respectively. The angle POR included between said lines is the angle of dip of the seam or the amount of dip.

The line OR is the line of true dip, while its horizontal projection OP is the direction of dip of the seam. The direction of dip is always measured by the horizontal angle NOP , in the horizontal plane. In like manner the line OX is the line of pitch of the seam, and its horizontal projection OY is the direction of pitch measured by the horizontal angle SOY . It is well to note that dip or pitch can only have one direction, while the strike of a seam may be given in two directions.

THEODORE SIMONS, Rossland, B. C.

Second Prize.—JAMES RADFORD, Springfield, Illa.

QUES. 608. *Cleats and Bedding Planes in Coal Seams.*—Explain the terms "cleats" and "bedding planes" in reference to coal seams and other stratified deposits. Also, state if there is any fixed relation between the direction of the principal or face cleats and the inclination of the seam.

ANS.—All beds of rock are divided by natural cracks or "joints," which are perpendicular or nearly so to the plane of stratification. There are usually two distinct sets of these joints or cleavages; the principal or main joints being crossed by lesser joints, more or less square with the main joints. Sandstones, slates and shales possess to a greater or less extent the same phenomena, which quarry men take advantage of just as miners do in the working of coal. Clays (fireclays) and other jointed deposits often have joints which follow no system and are hence called irregularly jointed deposits. Rock joints generally occur in regular, definite directions. The main joints or principal cleats are usually parallel with the axes of the folds or undulatory surfaces of the basins, saddles or areas containing them; but deflections and variations are very common in some coal fields, particularly those much disturbed by faults.

The principal or "face cleats" or "backs" as they are sometimes termed by the miners, cut the coal perpendicular to the stratification or nearly so, and are usually more or less parallel to the strike of the seam; while the lesser or "end cleats" as a rule run parallel with the dip of the seam; but as stated above, geological disturbances vary this rule, giving no fixed relation between the direction of the cleats and the inclination of the seam.

Bedding planes are cleavage planes or partings in the plane of stratification, and represent pauses in deposition, or changes in the character or composition of the sedimentary materials which were deposited in the water. A seam or bed of coal is invariably a series of parallel flat layers or benches of coal of varying quality,

hardness, structure, etc., grouped together so that they practically constitute one seam. These different benches are separated by cleavages or bedding planes and are of varying thicknesses, materials and extents. The bedding planes being planes of stratification are approximately at right angles to the cleats or joints, and are of great advantage to the miner in preparing his coal for the car.

THOS. ENGLISH, Streator, Ill.

Second Prize.—THOMAS CHARLTON, West Leisenring, Penna.

QUES. 609. *Surveying, Precautions Necessary When Surveying With Magnetic Needle.*—What precautions are necessary in surveying with the magnetic needle, in presence of iron or where attraction is liable to exist? State by what means such a survey may be made fairly reliable.

ANS.—Where local attraction exists, whether known or unknown, the bearing as indicated by the compass at one end of a line will differ from that read at the other end of the same line. By reading and noting the magnetic bearings of both backsight and foresight, at each station, the angle included between two consecutive lines or the angle of deflection at each station can be computed correctly regardless of local attraction. The angle of deflection so obtained, at each station, should be used to check the bearings of lines at all the stations of a needle survey. Assuming that the true bearing of the line from which the survey emanates is known, the true bearings of the lines of the compass survey may be computed by this means, and the survey made fairly reliable thereby.

THEO. SIMONS, Rossland, B. C.

Second Prize.—E. MCCORMICK, Siegelton via Luning, Nevada.

QUES. 610. *Ventilation, Effect of Splitting the Air Current Upon the Speed of a Fan.*—The power remaining the same, what effect will the splitting of the air current into two equal splits have upon the speed of the ventilator? State the reasons for your answer.

[A number of replies were received to this question; but though the conclusions were correct in some of them, the reasons given were in error. This suggests the advisability of answering question 624 first, after which question 610 will be answered more readily.—EDITOR.]

QUES. 611. *Furnace Ventilation; Splitting, Pressure Constant.* The circulation in a certain mine is maintained by means of a furnace at the foot of the upcast, but the quantity of air is insufficient for the thorough ventilation of the mine. If it were possible in this mine to divide the air current into two equal splits, would the quantity of air in circulation be doubled by this means? Give the reasons for your answer.

ANS.—The mine pressure remaining the same, the volume of air in circulation will be more than doubled, for the volume of air in each split, pressure remaining the same, will increase as the square root of the number of splits; since for the same perimeter and area, the quantity varies inversely as the square root of the length of airway; and when dividing the original airway into any number of equal splits, the length of each split is inversely as the number; therefore the quantity of air circulating in each split will vary as the square root of the number of splits. Calling the number of equal splits n , the total quantity of air circulating in all the splits after the division, will be $n\sqrt{n}$ times the original quantity. Therefore, if 10,000 cubic feet of air per minute were going through the undivided airway, and this airway be now divided into two equal splits, the total volume in circulation would be (mine pressure remaining the same) $2\sqrt{2} \times 10,000 = 28,284$ cu. ft. per min.

These are said to be the largest crushers ever built and the heaviest. The company also advertises very large rolls 48 in. $\times$ 18 in., and 60 in. $\times$ 24 in.

History of Working Siberian Mines.

The working of Siberian gold mines dates back only to the middle of the eighteenth century, at which period the first auriferous veins were discovered in the Urals and in the government of Archangel. Gold was discovered in the Ural Mountains in 1744. Several veins situated on the banks of the River Beregovka were worked with varying success from 1800. In 1895, the output was 19.46 poods (703 pounds). In the southern Urals, the first gold reef was discovered in 1799. The Kothkar reef yielded in 1894 about 85 poods (3,089 pounds).

Toward the close of the period 1870-1879, reefs were discovered in the government of Yenisei and the province of Transbaikalia. In 1894-95, gold-bearing strata were found in the district of Marunsk, in the government of Tomsk.

In 1866, the Amur Province was opened to private trade; two years later, mining was begun on the concessions belonging to the Upper Amur Mining Company, in the basin of the Djalinda. At the same period, explorations were set on foot in the Maritime Province, and in 1871 the first gold was taken from mines belonging to a Mr. Yetukof, in the basin of the Amgoun. During the season of 1897, the Amgoun Mining Company treated 10,834 cubic sagens of gravel, from which about 55 poods of gold were extracted, giving an average of 7.825 grams to a cubic meter. On the other hand, the Amur Mining Company took from placers 734 pounds, showing an average of more than 17.06 grams to a cubic meter.

In 1896, the Government dispatched to the shores of the Sea of Okhotsk an expedition which, according to the latest news, has found rich alluvial drifts. There have recently arrived at this port direct from the United States six practical American miners under the auspices of the Russo-Chinese Bank. They are supplied with modern machinery, are men of experience, and go to the Yumen, where rich discoveries are reported. In conversation with one of them, who last winter prospected in the Yukon, Alaska, the idea was emphasized that the whole region about Anadirski and the extreme eastern range of the Stanovoi Mountains, near Bering Straits, would prove as rich as the Cape Nome region, since it was of analogous formation.—U. S. Consular Reports. Translation from book by Baron de Batz.

Decision Sustaining W. A. Lattimore's Patent for Lamp Attachments.

The Lattimore Mfg. Co. has issued the following circular:

"We beg to advise you that in a recent suit brought by our Mr. Walter A. Lattimore, in the Circuit Court of the United States within and for the Southern District of Iowa, Eastern Division, the Lattimore Patent No. 415,720 was sustained, the same having been also adjudicated in the United States Circuit Court of Appeals, Eighth District, December Term, 1899, and testimony is now being taken before the Master in Chancery, appointed by the Circuit Court, to ascertain the amount of damages and profits due the Lattimore Co. for such infringement.

We have heretofore been lenient with dealers who have been handling infringements of our patents, but we now beg to notify the trade that all dealers or retailers handling such infringements hereafter will be summarily dealt with, the same as the manufacturing infringer, and all users or sellers of infringing lamp attachments will be equally liable to us for profits and damages, and we have instructed our attorneys, Messrs. Wiedersheim & Fairbanks, of Philadelphia, Pa., to move for a preliminary injunction at the proper time against all such infringers. We trust that any further legal action on our part will be unnecessary, as we have no intention of annoying our bona fide customers, who handle our goods in the regular way, but every dealer or user infringing our patents will be promptly prosecuted.

Very respectfully,

St. Clair, Pa.

LATTIMORE MFG. COMPANY.

TRADE NOTICES.

The Rand Drill Co., of New York City, has received from the Paris Exposition the Grand Prize and Gold Medals.

The Bethlehem Steel Co., has discontinued its St. Louis office 502 North 2nd St., and the territory hitherto covered by that office will be handled from the Chicago office of the same company.

The Ingersoll-Sergeant Drill Company of New York has received the Grand Prize at the Paris Exposition for its mining exhibit, the gold medal constituting this prize being the highest award given.

The Jury of Award at the Paris Exposition has granted The Bristol Company, of Waterbury, Conn., a silver medal for its exhibit of recording electrical instruments and also have given honorary mention to its recording steam and pressure gauges.

The Jeffrey Manufacturing Company of Columbus, Ohio, was awarded a gold medal, at the Paris Exposition, covering its line of elevating, conveying and mining machinery. No doubt many of our readers who have enjoyed a visit abroad this summer have had the pleasure of seeing the exhibit of this company.

Messrs. James McCrea & Co., 15 and 17 S. Canal St., Chicago, have just issued a new catalogue showing the Climax steam joint clamp. They report an increase of 100 per cent. in their business thus far over last year, and that the clamp has been adopted by the largest consumers in the country. Catalogues will be furnished upon application.

The Tamaqua Mfg. Co., of Tamaqua, Pa., makers of coal washing machinery, and mining tools has found it necessary to have more room. A new office building 22' x 20', 2 stories high has just been completed, which will be used also for the drafting department. The old office rooms will be utilized for additional machine shop room.

The International Boiler Works Co., Stroudsburg, Pa., has almost completed an office building 30 ft. x 35 ft., located some 500 feet distant from its boiler shops. The need of more room, as well as the desirability of being farther away from the noisy pneumatic riveting machines, compels the erection of this building. The trade of this company has nearly doubled in the past 14 months.

As an instance of direct returns from advertising, the Burt Mfg. Co. of Akron, Ohio, reports that it is crowded with orders as the result of an illustrated notice of the Burt exhaust head, which recently appeared. "Any article of merit" said Mr. Warden, manager of the company, "can be pushed successfully through judicious advertising in the trade journals, as we have demonstrated, to our own satisfaction, at least."

The Curtis & Curtis Co. of Bridgeport, Conn., manufacturers of pipe cutting and threading machinery, has just received a cable from its Paris agents, that the Forbes patent die stocks, of which an exhibit was made at the Paris Exposition, have been awarded the grand silver medal, by the board of award. This is naturally very gratifying to the Curtis Co., as the machines exhibited were in competition with others from all parts of the world.

One of the most profitable post offices in the United States is that at Scranton, Pa. The volume of business is unusually large and is steadily increasing, the figures for the first six months of the present year showing more than double the business for the same months in 1893. This is due principally to the rapid growth of The International Correspondence Schools. Seven years ago the schools' postage was barely five per cent. of the total but now one-third of Scranton's postage is paid by the I. C. S. Their postage has increased from an average of less than \$400 to over \$5,000 a month.

The S. Flory Mfg. Co. of Bangor, Pa., has been compelled to add to its plant, and recently it completed and moved into new offices in a brick building 44 ft. x 42 ft., three stories high. This building is provided with four fireproof vaults, and all modern conveniences. On the street floor is a spacious stock room, or salesroom. The company has also about half completed a brick addition to its machine shops, which will, when finished, add about 50% to the present capacity of the works.

The rapid growth of the export business of the B. F. Sturtevant Co. of Boston, Mass., manufacturers of blowers, heating and drying apparatus, engines, forges, electrical equipment, etc., is well exemplified by recent foreign orders for forges which aggregate 200 for Japan, 75 for Russia, 40 for Germany, 32 for Canada, and 24 for Sweden, in addition to large numbers distributed through its London and Continental stores. Domestic demands have likewise increased in the same line during the past few months, large forge equipments having been furnished to several ship building and locomotive shops in the United States.

The manual training, trades and technical schools have also been placing some large orders with this company.

Morse Williams & Co., Philadelphia, Pa., one of our largest manufacturers of elevators, report two particularly large contracts for the month of August—one from the Union Passenger Station at Pittsburgh, consisting of five hydraulic passenger elevators; two hydraulic passenger and freight elevators; six hydraulic freight elevators of the plunger type, all made with the latest improvements and best approved designs. Another large contract from the terminal station, Chesapeake and Ohio Railroad, for two hydraulic passenger and two hydraulic freight elevators. The Morse Williams Co. is among our most progressive manufacturers, and is well equipped for furnishing elevators suited to every purpose. The company is thoroughly informed as to every improvement in its special line of manufacture, and gives perfect satisfaction to its many patrons.

The Bethlehem Steel Company received on Sept. 1st a telegraphic order for a port propeller-shaft to replace the one which broke in the Plant Line steamship "La Grande Duchesse" while off Halifax recently. The owners of the vessel specified that the shaft should be made of fluid-compressed open-hearth steel, forged under hydraulic pressure, annealed and rough-turned, and the order was booked for shipment Sept. 11th. The shaft measured 32 feet over all, was 13½ inches in diameter, and the shipping weight was 15,458 lbs. It was taken in hand under emergency instructions and went forward Sept. 6th, five days in advance of requirements. Among the other orders recently booked by the same company are spare propeller-shafts for the steamers "Ponce" and "San Juan" of the New York & Porto Rico Line; eight forged hollow shafts of fluid-compressed open-hearth steel for use in Cuban sugar mills; and a large number of gun barrels for the Winchester Repeating Arms Co. and Colt's Patent Fire Arms Co.

The Borden & Selleck Co., 48 to 50 Lake St., Chicago, manufacturers of conveying machinery of all kinds, and general agents for the Howe scales, reports being behind on orders for scales and warehouse trucks. The company looks for continued good business through this year, except in sections where crops are poor. Among recent orders completed or under construction, taken by the company are the following for conveying machines: Soo Line, freight handling conveyors run by a Howe 30 h. p. gasoline engine for transferring freight at Gladstone, Mich.; Rutland Transit Co., new warehouse equipped with five freight carriers on incline for handling freight from dock to freight house and to boats; coal handling machinery and coal screens, including rope transmissions and gasoline engines for the following: Koenig Coal Co., Detroit, Mich.; O. S. Richardson & Co., Chicago; Uhrig Fuel Co., Milwaukee; North Ave. Fuel Co., Milwaukee; C. Reiss Coal Co., Ashland, Wis.; and H. M. Benjamin Coal Co., Milwaukee, Wis.; coal and ash handling machinery for the St. Louis Refrigerator Co., St. Louis, and for the Evansville Cotton Mfg. Co., Evansville, Ind.

The proof of the pudding is in the eating of it, and the best testimonial of the value of any machine is its continued and increasing use. The Thornton N. Motley Co., Sole Licensee for Eastern United States and foreign countries for the Jackson hand-power rock drill report recent purchases of this drill by the following firms: Columbian National Railway Co., Bogata, Columbia, S. A.; 2 drills; Niagara Gorge Railway Co., Buffalo, N. Y.; Peninsular Railroad Co., of Mexico, Progreso, Mex.; Spanish-American Iron Co., Santiago, Cuba, 2 drills; Davis Coal & Coke Co., Thomas, W. Va.; Messrs. Van Roosbroek & Co., Brussels, Belgium, 2 drills; Crawford Mining Co., Hazel Green, Wis.; Secretary of Public Works, Tegucigalpa, Honduras; Engineer of Electric Commission, Baltimore, Md.; H. Glaenzer & Perreaud, Paris, France; Arkell & Douglass, New York, for Australia; Dayton Coal & Coke Co., Dayton, Tenn.; Knauth, Nachod & Kuhne, New York, (For Germany), 2 drills; Arthur F. Easton, Perth, W. Aus.; Nichel Copper Co., of Ontario, Ltd., Worthington, Ont.; Harbison & Walker Co., Pittsburg, Pa.; Lawrence B. Gray, Paramaribo, Dutch Guiana; The Michigan & Pacific R. R. Co., Ltd., Zitacuaro, Michoacan, Mexico; R. W. Cameron & Co., (For West Australia), 15 drills. This same company deals in all sorts of railroad equipment, railway, steamship, mining, and contractors' supplies and is prepared to accept contracts for any materials included under these heads at very short notice. Its catalogue contains numerous testimonials from those who have had extensive experience in the use of these drills. Its New York office is 43 John St., and its London office 37 St. Mary Axe, E. C.

The Diamond Drill and Machine Co., of Birdsboro, Pa., the well known makers of the Royal crusher and of diamond drilling machinery, has recently completed and moved into a new office building. This is a brick structure 2 stories high, having a ground area of 90 ft. x 40 ft. and equipped with all modern conveniences. These increased facilities will greatly add to the company's already excellent plant.

ROCK DETERMINATION.

The Western Editor of MINES AND MINERALS will, without charge, examine and name, so far as possible, samples of rock sent him, the answers being sent by postal card to the sender of the specimen. He will only undertake to name average rocks, such as can be fairly determined at sight; and microscopic or chemical analyses will not be attempted; neither is it always possible to determine with absolute precision and certainty a small sample, or one decomposed and oxidized, and with such samples the sender must be content with the provisional determination that it *APPEARS* like such and such a rock.

Questions involving an opinion on mining property, for which an expert would be entitled to a fee, will not be answered, but advice that will aid the prospector will be given.

The following conditions must be observed by those sending specimens for determination:

The specimens should be fresh and about 2 inches square.

Each should be distinctly labeled.

The name and address of the sender, written very distinctly, must be enclosed in the package.

The package should be sent prepaid to Prof. Arthur Lakes, Room 608 Boston Building, Denver, Col.

A letter should accompany the specimens describing the locality, mode of occurrence of the rock and other facts, and rough sketches may accompany such descriptions.

Samples will not be returned unless by request, and where stamps are enclosed to cover postage or expressage and cost of packing.

Igneous Rocks. Andesites.

Andesite is a lava so named from its abundance in the Andes Mountains. The general appearance is that of a rather fine-grained rock of a gray, lilac, maroon, or reddish color, speckled profusely with little white and black minerals, which on closer examination prove to be small felspars hornblende and more rarely mica.

A typical specimen is of a lavender gray color, of rather a fine-grained texture, speckled all over with small white crystals of andesine felspar, from $\frac{1}{16}$ to $\frac{1}{8}$ of an inch in length. Interspersed with these are small black crystals of hornblende. The ground mass in which these crystals are set seems to the eye, to be an amorphous, lilac paste of felspar.

Another typical specimen from the Toltec Gorge, Colorado, is a pale lavender gray rock, speckled with crystals of black mica, some of which are of a bronze or copper tint. Amongst these are also some longer black crystals of hornblende. The ground mass appears as a pink paste of felspar, in which are set numerous small transparent, glossy, oblong crystals, of andesine trichite felspar.

A third specimen is a gray rock with much larger crystals of white felspar than the former, set in the ground mass. The rock sparkles with little black crystals of mica, and would be called a mica andesite.

DIORITES AND PORPHYRITES.

By development of a granular, coarse, or granite like texture, the andesites grade over into the generally older eruptives called diorites or porphyrites.

The typical diorite is a somewhat fine-grained, gray granite-like rock that might readily be taken for a fine-grained granite.

There is no true ground mass apparent; the rock seems made up of an aggregate of evenly divided small hornblende and white plagioclase trichite felspar crystals.

Another variety is very dark from the preponderance of hornblende in it. Its appearance is that of a greenish black rock spotted all over with minute white felspar crystals, and very distinct small crystals of hornblende. The ground mass is fine grained and of a darker gray tint made up of a "pepper and salt" of minute felspar and hornblende crystals.

A diorite containing distinct crystals of quartz in addition to the other minerals would be called a quartz diorite. From the distinctness of the larger crystals and their being porphyritically set in the finer grained ground mass, this would be called a porphyritic diorite, or porphyrite. Sometimes with the microscope you may observe the little parallel striae or lines on the felspars, which are a characteristic of the plagioclase, or trichite felspar. This felspar is the main characteristic of the rock, distinguishing it from syenite and granite, which it otherwise resembles, the felspars in these latter being orthoclase.

An olive or dull sage green tint often appears on the surface of this rock due to the oxidation of hornblende, hence the rock is often designated as "greenstone."

Andesite is an effusive lava, occurring in lava flows on the surface, issuing from dikes or craters. Diorite belongs to the intrusive or Plutonic rocks that have rarely reached the surface. It occurs in dikes and intrusive sheets and forms the bulk of most of our great laccolitic mountains, such as the Henry and others on the border of Utah, and the La Platas and Elk mountains in Colorado.

Mr. Cross also includes among the porphyritic diorites, or porphyrites, the great intrusive sheets of porphyry at Leadville, which we have been in the habit of calling quartz porphyries.

From this it would appear that the greater proportion of our so-called porphyries in Colorado, of an intrusive character may be grouped under the "porphyrite" family, and that between andesites, diorites, porphyrites and so-called porphyries there is a very close relation.

ANDESITE BRECCIA AND TUFF.

One of the commonest forms of andesite in the West and especially in Colorado, is not so much the massive rock itself, as the rock broken up into fragments and recemented again with its own material, forming what is called andesitic breccia, when very coarse, and andesitic tuff, when fine, like a coarse sandstone. These forms were produced by explosive eruptions, from explosive vents. The first explosion of a volcano is commonly very violent, the stopper of the throat is thrown into the air and into fragments, some of which fall around the flanks of the crater, whilst others fall back into the orifice and are again and again shot upwards. By this process and the friction against one another in the column of steam, the lava is reduced to very small fragments, or even to impalpable dust, and when later the steam cloud condenses and falls, it brings down with it a shower of these fragments and dust, and sweeps down over the flanks of the mountain in a hideous mud flow, gathering up pieces of all kind and sizes of rock into its muddy embrace, filling up ravines, overwhelming villages and, it may be, overtopping low hills and filling river courses. Such material when it comes to rest "sets" in the adobe form we know as tuff or breccia such as covers the region around Cripple Creek. Sometimes a volcanic orifice is opened near the border of a lake, and the explosive showers of dust fall into the lake, and becoming mud form a semi-stratified tuff deposit of the finest shale, or of coarse conglomerate or breccia. Such we find in the Tertiary lake beds of Florissant a few miles north of Cripple Creek, where the fine tuff shale encloses exquisite impressions of the leaves of trees growing by the lake at the time of the eruption, the fossil trunks of the trees that bore them still standing erect and fossilized, in the mud in which they grew, now turned to shale. The same "tuff" shales also contain well preserved remains of various insects. Alternating with these shales are coarser beds of larger volcanic flows or volcanic breccia. Dr. Cross considers the vast breccia beds of the San Juan region to have been poured out from explosive andesitic vents and to have found their way into an extensive lake. The volcanic breccia beds of San Juan form beds whose cliffs are over a thousand feet high showing the vast amount of material extruded from the volcanic orifices. The appearance in the distance of these great breccia sheets in the San Juan is that of dull leaden gray, sombre masses, often rounded into curious forms by erosion. On closer inspection we see they are made up of more or less angular blocks of andesite usually of a dark lilac or lead gray color, cemented together by a paste of more altered andesite of an olive greenish tint resulting from the oxidation and alteration of the dark silicates, the hornblendes, micas, etc. A cross-section of a block of these andesite breccias with its different colors, lilac, maroon, gray and green, is very handsome and like a mosaic pavement.

The tuffs on the other hand are hardly distinguishable from ordinary coarse or fine sandstones. At Cripple Creek these breccias and tuffs are much oxidized and altered by hot water and subsequent surface action, and it is only now and then that we can detect the material of which they are made. The general fragmental character of the rock easily distinguishes it from phonolites and others. A few massive bodies of andesite occur at Cripple Creek showing distinct porphyritic crystals of felspar and hornblende, as, for example, at the Anaconda mine. In South Park, Colorado, is a remarkable mountain formed of hypersthene andesite called Buffalo Peaks. It is really a capping flow of andesite resting upon other strata. This sheet is perhaps 500 feet thick and shows in parts a columnar structure like basalt. The flow doubtless covers the throat of the volcanic vent from which it was extruded. The rock is called hypersthene andesite from hypersthene, a dark form of pyroxene, very closely allied to

ANDESITIC BRECCIA.

PORPHYRITIC DIORITE. (PORPHYRITE.)

ANDESITE BRECCIA RESTING ON THE ALGONKIAN QUARTZITE, MEARS ROAD, SAN JUAN.

augite. Besides the massive, there are also tuffaceous beds in the lower part of the mountain, some of them loose, friable ash beds, others contain a large amount of pearly glass.

These beds of tuff contain fragments of granite sometimes 6 feet in diameter, shot up from the granite throat of the volcano at the time of its explosive eruption. Granite fragments occur similarly in the Cripple Creek tuffs. The pebbles included in these tuffs represent as many types of massive andesite as are indicated by the various beds. The thickness of these tuff beds of 1,500 feet shows that there was a long explosive period before the massive lava capping the peak poured out.

These tuffs rest on Carboniferous limestone at the base of the mountain. The solfataric or hot spring action, which succeeded the eruption is well shown in the limestone being thoroughly silicified and coated all over with opal and chalcedony like melted wax or candle grease. Deposits of a beautiful white porcelain opal occur among the tuffs. Some of the rocks are coated with a frost-like or glassy scum called hyalite, and on the summit are holes in lava formed and vitrified by lightning.

ANDESITE IN THE ANDES.

As to its occurrence in the Andes Mountains, whence it got its name. Darwin, in his geological observations says: "A rock of Plutonic origin and highly important in the history of the Cordillera from having been injected in most of the great axes of elevation and from having been instrumental in metamorphosing the superincumbent strata has been called by some authors andesite. It consists mainly of well crystallized white albite felspar, of less perfectly crystallized green hornblende, often associated with mica, chlorite and epidote (both green secondary minerals) and occasionally with a few grains of quartz. Where the mica and quartz are abundant, the rock cannot be distinguished from granite. These andesitic rocks form mountain masses of a white color."

"In their general outline and appearance, in their joints, in their occasionally including dark colored angular fragments of some pre-existing rock, and in the great dikes branching from them into the superincumbent strata they manifest a close and striking resemblance to masses of common granite and syenite. I never saw however, in these andesitic rocks those granitic veins of segregation which are so common in true granites. Andesite occurs in three places in Terra del Fuego. In Chili from St. Fernando to Copiapo, a distance of 450 miles, I found it under most of the axes of elevation. In a collection of specimens from the Cordilleras of Lima in Peru, I immediately recognized it and it occurs in Eastern Kamtschatka. From its wide range and from the important part it has played in the history of the Cordilleras I think this rock has well deserved its distinct name of Andesite."

ANDESITE AS A MINING ROCK.

Andesites are a very important class of rock from a mining point of view. Formerly granite was the favorite rock amongst miners, as most fissure veins were supposed to occur in it. Now, in the West, of late years, especially since the discovery of Cripple

DIAGRAM ILLUSTRATING THE SUCCESSION OF ANDESITIC VOLCANIC FLOWS AND OTHER FORMATIONS RESTING ON UPTURNED STRATA.

Creek's gold deposits in andesitic breccia, more and more attention has been given to this rock and its occurrence. It is proving to be, of all lavas, the most singularly prolific one in gold, not merely in Western America, but in other regions of the world. Generally speaking when gold is found to be associated with lava rock at all, that rock proves to be one of the andesite family. In Colorado beside the gold being found in andesitic breccia at Cripple Creek, andesite from a volcano at the Rosita mining region is the principal lava there also giving its gold. Nearly all the fissure veins of both silver and gold of the San Juan region are in this character of eruptive lava, the extent of which in

Western Colorado covers thousands of square miles. The same variety of rock prevails together with diorite, its relative, along the gold belt of the Pacific coast, and in Idaho Territory. It is not too much therefore to call it the gold-bearing lava.

IOWA COAL-MINING METHODS.

The Character of the Coal—Its Influence on the Methods of Mining—The Systems in Use.

Written for MINES AND MINERALS by J. T. Beard, C. E., E. M.

The Iowa coal field is the most northwestern portion of the central coal basin of the United States. The seam of coal most generally worked throughout the State lies at an average depth of 200 feet below the surface of the prairie. The coal field of Iowa covers an area of about 10,000 square miles in the southern portion of the State. The seams present numerous outcroppings in the larger river beds. Geologically it forms the same deposit as the Missouri and Illinois basin. The coal lies in lenticular-shaped basins extending in a northwesterly and southeasterly direction, thus dividing the entire field into a series of local basins varying in width and length. The faults are almost without exception those due to erosion. These faults for the most part have the same general direction, from northwest to southeast. The seams of the entire field present little or no inclination. The floor of the Iowa coal is generally a fireclay, which is hard when dry but becomes soft and yielding when the mine is wet.

The general character of the overlying strata is a succession of shales, sandstones, and limestones of varying thickness but of a generally yielding nature, forming a strong and good roof for mining purposes. There is no gas found in any part of the State.

Character of the Coal.—There are in most parts of the coal field three distinct seams, of which, however, only the lower seam is generally worked. The thickness of this seam varies from 4 to 7 feet. The character of the coal varies from medium soft to a hard brittle coal that shoots with difficulty. The coal is a bituminous coal of excellent quality for steam purposes as well as for domestic use. In certain localities some sulphur occurs in the form of sulphur balls and streaks of pyrites, but this is only local. There is quite frequently overlying the coal seam a draw slate which comes down readily when the coal is taken out. While this is an advantage in entry work, as the fall of the slate increases the height of the entry, it often makes the roof in the rooms very heavy and difficult to manage, and is the cause of frequent accidents. In the southern portion of the State, around Centerville, there is a large area of a very uniform thickness of good coal. In this section the seam is divided near its center by a 2½-inch clay parting. The coal, also, in this section has a definite cleat, often requiring the breasts to be driven in a given direction. This feature does not occur elsewhere in the State. The Centerville seam is not generally believed to be of the same age as that of the seam worked in other localities. It has been found to exist, however, as far north and east as Monroe county. The coal of this seam is of excellent quality. Careful borings are now being made near Centerville to prove the presence of the lower seam in that locality. A characteristic of the upper Iowa seams is the purity of the coal which makes possible the working of these thinner seams in many localities.

Thickness of Entry and Room Pillars.—The conditions with respect to floor and roof are often such as to induce a squeeze, if sufficient care is not given to the providing of sufficient width of entry and room pillars. This is particularly the case when a hard sandstone or rock cuts out the roof shale. The usual thickness of entry pillars adopted is, for the main roads 6 to 8 yards, for the cross-entries 5 to 6 yards, and for room pillars 3 to 5 yards. It is customary, however, in approaching the point where a cross-cut is to be made in a room pillar, to draw in gradually, at this

FIG. 1.

point, in order to decrease the thickness of the pillar and to lessen the length of the crosscut.

Systems of Working.—The systems of working generally employed are the *room-and-pillar* and *longwall*. The room-and-pillar system is slightly modified, at some of the mines, by driving up narrow rooms with wide pillars, and drawing back the pillars. This is a practical system of *pillar and stall*. It is adopted, however, only locally, in some few instances. Another modification of the room-and-pillar system quite frequently found is that of driving *double rooms* with a wide breast varying from 15 to 20 yards in width, separated by pillars of 8 or 10 yards in width (see Fig. 1). A roadway is carried up each rib. Still another modification of the room-and-pillar system is one in which rooms are driven in sets, there being from 6 to 8 rooms in a set.

Fig. 2.

The breast in these rooms is carried forward in one continuous line, there being two fast ends requiring to be cut in each breast. Each set of rooms thus forms practically a separate panel in which the coal is mined longwall. This is, therefore, in some respects a modification of the panel system. The panel breast is often spoken of as "a longwall breast" in such cases; but it cannot be considered as longwall work, within the general significance of the term *longwall*.

Room-and-Pillar System.—In this system the main haulage roads run both ways from the shaft, and from these cross-entries or haulways are driven to the right and left. The double-entry system is almost invariably used in the larger mines; the single-entry system being used only in some local mines. Rooms are driven off both entries of each pair of cross-entries. The rooms are generally spaced from 33 to 40 feet, center to center. The breasts usually vary from 8 to 10 yards in width, with pillars varying from 3 to 4 yards. The rooms vary in length from 50 to 100 yards according to the character of the roof and floor. The usual practice is to turn the rooms narrow for a distance of 3 yards and then widen upon the inbye rib, at an angle of 45°, till the full width of the breast is obtained. The road is carried along the straight rib. A plan of a typical Iowa mine of this description is shown in Fig. 2.

Longwall.—The system of longwall generally employed is that in which a main-haulage road runs in each direction from the foot of the shaft. From this, diagonal roads are turned upon both sides of the main road, at an angle of 45°. Working places are opened off these diagonal roads at an angle of 45°, or parallel to the main haulway. These working places are spaced about 10 yards apart, and are usually driven a distance of 50 to 60 yards, when they are cut off by another diagonal road.

Pillar-and-Stall Work.—This is only employed locally where the conditions of roof and floor require it. The stalls, though sometimes turned off the entry at their full width (4 yards), are usually turned narrow and widened inside. The thickness of the pillar varies from 5 to 8 yards. The stalls are usually driven from 30 to 40 yards in length and the pillars drawn back. The stalls are sometimes driven in pairs, when a wider pillar, varying from 8 to 10 yards, is carried between them.

Double Rooms.—The method of driving double rooms or breasts is often employed. The mouths of the rooms are usually spaced 40 to 50 feet apart and are turned narrow off from the entry for a distance of 4 or 5 yards. A cross-cut is then made connecting these openings in pairs and a breast of about

16 yards is driven up a distance varying from 50 to 60 yards. The width of the pillar separating each pair of rooms varies from 12 to 15 yards.

Panel Breasts.—This method, shown in Fig. 3, is one quite frequently adopted where the conditions are such as to induce a squeeze. Rooms are turned narrow off the entry in the same manner as in the room-and-pillar work, but are arranged in sets of from 6 to 12 rooms in a set. A large pillar is carried between each set of rooms. The thickness of this pillar will vary from 10 to 20 yards, according to the conditions inducing a squeeze, with respect to roof and floor. When the rooms have progressed a short distance from the entry, those in each set are connected by crosscuts and a longwall face is carried forward from this point. There are two fast ends requiring to be cut at the outer ribs of each set of rooms. Packs are built and the roof allowed to settle the same as in longwall working. The wide pillars separating each set of rooms are won later, after roof settlement has taken place.

Ventilation.—The system of ventilating the workings usually employed is that of conducting the air to the inside workings, by means of an air course forming the back entry of each haulage road. From this point it is carried along the face of the rooms, through the breakthroughs or crosscuts in the room pillars, returning thence to the haulage road, which is usually made the return airway. When, however, the mine is ventilated by means of a furnace or an exhaust fan, the intake airway is usually made the haulage road in order to avoid doors at the shaft bottom. It is customary to ventilate each district of a mine separately by means of air-bridges or air-crossings whenever the development will warrant the expense of building the crossing. For this purpose overcasts are generally used built of wood.

Fig. 3.

Siberian Climate and Agriculture.

There is no doubt that the climate of Siberia is more rigorous than that of any other country in the same latitude. The northern shore is washed by the Arctic Ocean, whence the polar winds sweep unimpeded over the whole country, while the great central Asiatic range shuts out the warm southerly and southeasterly breezes. Hence, the regions of Siberia enjoy a more inclement and less equable climate than places of corresponding latitude in Europe and North America (except the northern placers in the interior of Canada, which, however, profit in summer by certain warm-air currents from Mexico and the Antilles which temper the climate to some extent).

Siberia may be divided from north to south into three great zones.

First. The polar zone, or the zone of the "Toondea," stretching from the polar seas to the polar circle, with outlines somewhat irregular. Vegetation in this region is reduced to grasses, mosses, and lichens. The soil is perpetually frost bound.

Second. The forest zone, extending from the polar circle to the fiftieth or the fifty-fifth degree of latitude, characterized by thick forests intersected by swamps.

Third. The cultivable zone, stretching south to the Chinese frontier. In this zone the summers are warm and genial. Wheat, rye, and oats can be grown, and stock raising may be carried on. Almost all of the efforts of the colonists have been concentrated here. This comprises at present the four governments of Tobolsk, Tomsk, Yenisei, and Irkutsk, leaving out of consideration their most northerly districts and the mountainous portions of the government of Tomsk, Yenisei, and Irkutsk lying near the Chinese frontier. It also includes the regions watered by the Amur and the Ussuri, sparsely populated at present, but rapidly being settled by immigration under the reduced rates on the Great Siberian Railroad now completed to Stretinsk, east of Baikal. This zone contains approximately 54,000,000 acres, with only 5,380,000 acres under cultivation. The system of cultivation is still primitive. The land is first cleared, the trees are felled, stumps are removed, or on the steppes the soil is merely plowed. The ground is next sown with wheat for two or three years consecutively. It is then allowed to lie fallow, and subsequently is again sown with wheat. This rotation is continued until the ground shows signs of exhaustion. The land is then left completely uncultivated, and other fields are tilled in the same careless manner.—U. S. Consular Reports, Translated from Book by Baron de Batz.

EXPLOITING A NEW PLACER FIELD.

Some of the Considerations to be Taken Account of, as Illustrated at Fairplay, Near Alma, Colorado.

Written for MINES AND MINERALS, by Prof. Arthur Lakes.

There is a certain charm as well as a good many peculiar difficulties to be met with in the opening up of an entirely new untouched property. It is fraught with all the romance and expectations of possible great things; no one knows, no one can tell for sure, and therefore there may be great things below the sod, and it is the tendency of the human imagination rather to exalt than depress future possibilities and grand uncertainties. Such is the case with an untried placer field covered at present by pasture, and fed upon by herds of cattle. It is proposed to transform this pleasing meadow from a farm ranch into a placer ground and to deluge the green sward with tons upon tons of dirty water, silt, mud and pebbles through the agency of hydraulic elevators and other appliances of modern gold placering. But before these mighty engines can be brought on the ground and before in fact the ranch is actually bought or leased a great deal of prospecting and probing, theorizing, speculating and surmising has to be done and efforts made first to find whether there is any right to expect gold under the sod; secondly, whether experiment shows there is positively any gold, and approximately how much on an average, and whether, taking all things into consideration, it will pay to work on a large scale after the ranch is bought or leased.

We will now describe or sketch the location of a typical new placer and its surroundings. The placer is on a certain ranch area in the broad flat flood-plain valley of the Platte River, about ten miles south of Fairplay in the South Park of Colorado.

South Park is an elevated meadow-like rolling basin, high up 10,000 feet in the heart of the Rockies of Colorado. In early geological periods it was for a long time an arm of the sea, or almost an inland sea, whose waters during many ages laid down in its basin on the granite flanks the whole known geologic series from the Cambrian, Silurian and Carboniferous or Paleozoic series of quartzites, limestones, grits and sandstones to the topmost strata of the Mesozoic, with the red Jura-Trias sandstones, shales and limestones below, to the marine Cretaceous sandstones, shales and limestone and coal-bearing strata above.

The Park is a basin scooped out of granite, and overlaid by

of two or three varieties of so-called porphyries or porphyrites, which appear to have had considerable influence in the deposit of ores of gold and silver at their contact with the metamorphosed sedimentary rocks.

Such are the geological surroundings from which the gold of the placers of the region and the placer meadows have been drawn. Looking up from the placer meadows in question we see the hills all around it on the north and west to be furrowed by deep cañons, cutting the Mosquito Range with all its aforementioned strata to the very core. These cañons all drain into the Park, and it is evident that whatever material the glacier or stream once occupying them carried out from them was carried into the Park, and the first coarse mass was dumped along the path of the cañon in the retreat of the ice and also at the entrance, while the remainder

PLACER WORKINGS, ALMA BASIN.

and finer material was washed down by the broad rivers of the time into the Park and there sorted and its gold deposited.

Foremost among these cañons is that at whose head, under Mt. Lincoln, are the various sources of the Platte River whose waters flow through the meadow in question. If we follow up the stream we arrive at Fairplay, where the glaciers from the foot of Mt. Lincoln appear to have dumped their great terminal and very coarse moraines. Through this, but not cutting down to bed rock, flows the Platte River. This placer ground has been worked more or less for the past 30 years by Chinese and others on a small scale, but no attempt till lately has been made to sound the placer deposit and find bed rock. This has now been successfully accomplished by the Cincinnati Co. at a point two miles below Fairplay and bed rock reached at 35 feet below the bed of the stream, making the entire thickness of deposit about 100 feet. This fact being ascertained the company is now laying extensive plans for working back down to bed rock the whole bed of the stream for several miles by hydraulic elevators and dredges. To accomplish this they have secured a powerful 300 ft. head of water on either side of the river some two miles up stream. The water will be carried down to work the nozzles in the elevator two miles distant. The pipes come in from streams on either bank of the main stream. One pipe 20" diameter coming in from the north side is connected with a 4-mile ditch, and another from the south side 30" in diameter is connected with a 2-mile ditch derived from the Sacramento River; they meet in a V shape and connect with the main pipe which is 32" diameter and which is carried along on trestles above the river bed, the river course being deflected by a dam till the elevator is reached. After this they may gradually work down to bed rock as far as desired up stream.

Leaving Fairplay and following the course of the stream up to the foot of Mt. Lincoln we find the whole way lined with rolling mounds of boulders left by the great Mt. Lincoln Glacier. At Alma, some ten miles from Fairplay, we find hydraulic mining in active operation under the charge of Mr. Fortune. Work has been successfully carried on here for many years upon banks of material which appear to have been laid down by the Mt. Lincoln glacier combined with tributary glaciers from Buckskin and other cañons all draining gold-bearing areas. The work here consists of cutting down banks by pipes and sluices and hydraulicking them to bed rock, as well as ground-sluicing them. An account of these typical hydraulic placers we gave in THE COLLIERY ENGINEER AND METAL MINER some years ago. The bed rock consists of a coarse

VIEW OF ALMA BASIN.

sedimentary beds of the Paleozoic and Mesozoic ages. These strata by the uplifting of the granite are tipped up all around the edges of the Park to the tops of the mountain ranges. These ranges have subsequently been deeply scored by glacial and river cañons, which debouche into the Park. Any one of these cañons shows on its cliffs a complete anatomy of the geological structure of these ranges, which we find to consist below of granite or gneiss traversed by quartz fissure veins, carrying locally more or less ores, and overlaid above by Cambrian quartzites, Silurian limestones and Carboniferous limestones, with locally a capping of Weber-grits of the middle Carboniferous. All these strata from the granite upwards are more or less traversed by igneous dikes

Weber-grit sandstone; on this and in its crevices the richest gold is found, and the bed rock is cut down several feet and thoroughly investigated with knives and brushes before it is abandoned. This bed rock, which lies at a gentle angle, is overlain by from 50 to 75 feet of gravel, consisting of sand, gravel and large and small boulders principally of porphyry, quartzite and granite. The gold is richer near the base of this gravel than in the upper portions, though all is worked from grass-roots to bed rock. The gold is fairly coarse and several good-sized nuggets have been found. We can follow the same placer formations to Montgomery and the Hoosier Pass at the base of Mt. Lincoln. Here the whole mountain has been cloven by glaciation in a stupendous cliff from summit to the river valley, showing the anatomy of the mountain, which consist, at the top, of a laccolitic body of quartz-porphyrity with dikes of porphyry ascending to it from the granite below and sending out wedge-like intrusive sheets into the sedimentary beds of limestone and quartzite overlying the granite. The granite itself is traversed from top to bottom by a series of large parallel pegmatitic veins of quartz and white felspar, several of which have been exploited and found to contain gold-bearing pyrites. Just at the foot of the cliff is a deep pond or small lake into which the Platte tumbles in waterfalls from a U-shaped glacial cañon at the back of Mt. Lincoln, where the stream has its source in several beautiful glacial lakes or tarns hollowed out of the solid granite by past glacial agencies. It has been thought by some that this deep pond or lake into which the waterfalls pour must contain a "pot of money sufficient to cover the whole indebtedness of the United States;" and several schemes have been thought of to coffer dam it and explore its bottom. But it is a curious fact that such inviting looking "pot holes" have in the experience of placer mining proven often very disappointing. They have often proven to be a clean worked out basin in which no gold was left deposited, and the gold that may have been carried into them is more often found washed and carried out of them a little further on the rim of the basin rather than in its depth. It is from this region, however, that the main source of the gold seems to have come, probably from porphyries, granites, and quartzites.

The success at Alma encourages the new undertaking at Fairplay in glacial placers and tempts the further undertaking in the glacial-river deposits of the Park and Platte Valley and of the placer meadow in question.

Returning again to our placer meadow. The surroundings and other considerations being favorable, the next point to consider is the meadow itself. What are the probabilities of gold beneath the grass, and if gold is there, in what paying degree? Over what area is it paying, what is the depth to bed rock and where are the principal channels? Many of these points will later be proved certainly by practical experiment, but before that, what can we say theoretically about it? First it is evident that the placer is a river deposit and not a glacial one, this is shown by the fact that the pebbles encountered are generally small and well-rounded by water rather than by glacial action. Secondly, as to the location of probable channels old and new. The meadow lies between two banks, one of red Jura Trias sandstone on the west, which is more or less hugged by the modern stream, and by a lofty hogback of Dakota sandstone on the east, the two banks being upwards of a mile apart. On the flanks of the eastern Dakota hogback there are no traces of pebbles, it is evident that the ancient stream did not swing to that side and the shore line deposits at its base appear to be shallow, so we need not look for the main channel on that bank; on the other hand, the red bank at the west to its summit is strewn with pebbles which are larger a great deal than those on the eastern rim and are often piled up on the banks; however the present surface of the meadow slopes toward the west side, it

is evident then that the deepest and main channel lies in this western direction and that here will be found the thickest and deepest deposit of placer material.

As to the general existence of gold over this tract, this can be ascertained in a preliminary way by panning the streams and water courses, by digging short holes here and there and by putting in short sluices, should these prove satisfactory. Then a more systematic prospecting should be carried out over a large area and for a considerable length of time. This should

be done by a systematic series of borings put down by an ordinary churn drill, not by a diamond-core drill as the latter will not work amongst loose debris. There are several patterns of churn drills, but the one that appears at present most popular is the Star drill.

These holes should be mapped out over the meadow and a record kept of panning at every foot or so, and the gold kept in labeled bottles and a diagrammatic record kept of the character of the material pierced. By this means also the depth and character of bed rock can be ascertained at various points and where gold is found on or in it. In this way an underground map can be made of the whole meadow, its values and bed rock. In this particular instance the geologist can form a pretty good idea of what the nature of the bed rock will be. He knows from its geological position that it will belong to the Jura-Trias period and will consist mainly of uptilted red sandstone and shales. The dip of these also he easily ascertains from the exposures on the banks; he finds this to be about 45° and to the east. In this uptilted condition they will prove fairly good natural riffles for catching and arresting the gold as it is borne side-long along their edges down stream, but not so good as if their upturned edges lay transversely across stream.

The ground having been well prospected for a period of several months and some certainty as to its value having been attained, the elevators may be ordered and placed on the premises. The Evans elevator of the Risdon Works of San Francisco appears at present to give the greatest satisfaction. The elevator should be located at the farthest down-stream locality of the meadow with a view to working up stream. Of the mode of working the elevator we shall speak later more fully in our description of its actual working at the Breckenridge placers. Besides the elevators at that locality there are various other machines being used, such as excavators and dredges, all of which have their peculiar merits and are adapted more or less for particular soils and locations. Some of these we shall describe in another article.

SODA SALTS AS BOILER COMPOUNDS.

What the Various Salts Are and the Effects They Have Upon the Various Substances Found in Steam Boilers.

By W. H. Edgar.

Through the courtesy of Mr. W. H. Edgar, President of the Dearborn Drug and Chemical Co., Chicago, Ill., we are enabled to publish the following answer to an inquiry addressed to that company relative to the action of various soda compounds often used in boiler practice.

The following salts of soda are soluble in water, more so in hot solutions and they will not precipitate out of solution until the solution becomes saturated so that it will not hold a larger quantity in solution, when the salt of soda will cake at the bottom or hottest parts of the vessel.

Caustic soda, commonly known as concentrated lye (sodium hydrate); *soda ash*, which is carbonate of soda and, when in crystal form, is known as sal soda or washing soda; *bi-carbonate of soda*, the same as carbonate of soda except it only has one half the quantity of soda, the other half being displaced by hydrogen; *sulphate of soda*, which is commonly known as Glauber's salts; *chloride of soda*, or table salt; *nitrate of soda*, found in large quantities in South America and used as a fertilizer, and also in obtaining or producing saltpeter; *fluoride of soda*, which is the combination of hydro-fluoric acid and soda; *phosphate of soda*, which is the result of the phosphoric acid and soda, etc.

Sodium salts are not volatile nor will they evaporate or carry over as a gas by distillation or sublimation, hence the soda found in the condensation, in the engine cylinder and through the steam system does not volatilize and carry over or pass over by itself; it is carried over mechanically and not chemically or physically.

If steam is perfectly free from moisture when delivered from the boiler, it will not contain or carry any soda, as it is the moisture which holds or contains the soda salt in solution and, if this moisture is left behind, we also leave all trace of soda behind.

If one pound of soda, that is, caustic, sal, or soda ash, or any salt of soda, were dissolved in a given quantity of distilled water and the water boiled and evaporated, the entire amount of soda would remain; there would be no loss whatever. You would recover all the salt you had in solution, except careless boiling causes the water to be spattered out of the dish; of course all solid body of moisture spattered and lost contains just so much soda. This is the only possible way you could lose any part of the salt you have in solution.

The term "salt" is applied to the combination of an acid radical and a base, which forms a neutral salt. Soda combined

with different acids forms sodium salts. Lime combined with different acids forms lime salts. In the same way magnesia or any other base combined with a corresponding acid radical forms a neutral salt, named correspondingly with the acid radical with which the base is combined. So the term "salts" means all such.

Soda ash, or washing soda, and caustic soda are used to make soap. Soap is the result of the action of the soda base combining with the fat or oleic acid, forming oleate of sodium. This gives us soluble soap. The carbonic acid gas, combined with the soda, as carbonate of soda or soda ash; or the hydrate combined with the soda as caustic soda, is easily and readily displaced by the oleic acid, the soda having a greater affinity for the oleic acid than it has for the carbonate or hydrate radical. This is called saponification. You know very well what soap would do in the boiler; you know its action in the water; it forms a suds; it foams. Now, the soda has the same action on the water without grease or soap. We do not, nor can we, get this action from a chloride, a fluoride or a nitrate of soda. These three, chloride, fluoride and nitrate belong to the same group; their physical and other peculiarities are very similar. The affinity between the soda and these acids is so great that it will not go to another acid radical, consequently we cannot saponify the water and cause foaming by the use of these salts nor by use of phosphate or sulphate. But a sulphate will give off to some extent, softening the water by breaking up into a hydrate when in a boiling solution.

If you introduce caustic soda or soda ash into your feed water, you saponify the water in your boilers, causing it to foam, to form suds, which breaks up and spatters the steam, and the water becoming more sudsy, the steam is spattered that much more, and these little, minute, solid sheets of water are virtually blown over. The great velocity with which the steam is leaving the boiler carries this moisture over mechanically and, when you have soda in solution, naturally any part of that solution carried over takes over just so much soda. Any grease or dirt that may be in the boiler or water will cause just so much more of this saponifiable condition, and therefore it will cause the foaming to be more violent.

Soda ash or caustic soda carried into the cylinder of the engine cuts the cylinder oil, forming soap with the animal or vegetable part of the cylinder oil and mechanically coagulates into a sticky, non-lubricating mass the mineral part of the cylinder oil; consequently your lubrication is destroyed. The same action takes place in a boiler where you have oil coming back in the returns. Soda carbonate and soda hydrate saponify the animal oil, forming soap, which gives you violent foaming, and at the same time it cuts and coagulates the mineral oil into a mass.

A word on oils. Where you are constantly buckling the tubes in a water tube boiler, or bagging the sheets in a tubular boiler, or the back ends of the tubes of a tubular boiler are constantly leaking, it is due to oil coming into the boilers with the returns. The animal or vegetable oil, combining with the lime and magnesia as oleate of lime and magnesia (most of the lime and magnesia being in the form of a carbonate) the carbonic acid is readily displaced by the oleic acid. These oleates of lime and magnesia are insoluble, because the oleic acid has combined with an insoluble base. This oleate of lime is formed on top of the water in little globular masses, which are very adhesive and sticky; they gather together, forming into a mass, and then become of the gravity equal to the gravity of the water and are carried buoyantly with the circulation. They always adhere mostly around the ends of the tubes or in the lower water tubes, because this substance has a greater affinity for the hotter metal than for the cooler parts of the boiler, adhering to a hot surface more rapidly. Being a perfect non-conductor of heat, it concentrates and checks the heat in these parts, preventing the water from absorbing the heat, consequently the metal is brought up to such a degree of heat that it melts; the pressure within forces the metal out, buckling the tube or forming a bag. The mineral oil combines with the lime and magnesia as a mechanical mixture in a coagulated, sticky mass, incorporating with and forming a part of the general mass, all of which is insoluble and very adhesive. This *mechanical mixture* is also formed with common salt (chloride of soda), or the fluoride or the nitrate of soda. Any one of these three will form a more sticky, tenacious, adhesive, coagulated substance mechanically with the oil, both mineral and animal, and in a hot solution far worse than the combination with lime or magnesia. This is formed because the affinity of the fluorine, nitrogen and chlorine with soda is so great that it does not break up but enters into a mass with the oil; so wherever you may be getting a little oil back in your returns, a fluoride or chloride of soda will cause your boiler to leak and bag more quickly and the action is more vicious than the action with lime.

When we say lime, we mean the natural scaling salts in feed water. Now, where you are using the average feed water, you have carbonate of lime and sulphate of lime, which form scale and, when you use ash, it is for the purpose of furnishing carbonic acid or carbonate to give you a double salt or enough carbonate to make your lime soluble as it originally was in solution as a bi-carbonate. But you readily see that you have your soda in solution, consequently you get the soda action, foaming, etc.

Hydrate is used because lime salts are soluble in an excess of the hydrate but this excess gives you the same trouble. Chloride of soda has no action on the lime, as the chlorine has a greater affinity for the soda than it has for the lime. Fluoride is introduced with the object of converting the lime carbonate and the lime sulphate into fluoride of lime which is a flocculent light precipitate. But you readily see that where the fluoride goes to the lime, the soda goes to the carbonate with which the lime was combined and leaves the soda ash in solution, so that at the end of two weeks or one month's run the solution in the boiler is saturated with soda ash. Consequently you get a soda action, the water is saponified and carried over, and the valves and connections are all eaten out from the same old soda action.

Then again the fluoride of lime, which is formed and which would remain as such in a cool solution, is broken up to a great extent in hot solution, due to high heat in a steam boiler, which the average chemist does not stop to figure and think of. When this fluoride of lime breaks up, you get the oxide of lime and free hydrofluoric acid. The hydrogen of the water combines with the fluorine, forming hydrofluoric acid and, the oxygen of the water goes to the lime, forming oxide of lime. This hydrofluoric acid liberated attacks the metal and eats the iron, it being much more corrosive and vicious even than sulphuric acid. The oxide of lime forms a scale just as readily as the carbonate, and therefore causes just as bad trouble.

Soda is so extremely cheap that the fakirs, who have a living to make, can afford to sell any preparation of soda and make a thousand per cent. profit; and, the prices that they get are such that all they need to do is to sell one or two kegs per week. They care not for your boilers and if they did, their knowledge would not help them out. They know nothing about what they are selling but they are good talkers and tell the same story as that with which all soda dopes have been handled in the last twenty or thirty years.

If you are going to use soda, buy your own. Phosphate of soda, whether it be tri-sodium phosphate or the other soda phosphates, is used with the same purpose in view; that is, of converting the lime carbonate and the lime sulphate into phosphate of lime, known or claimed to be tri-calcium phosphate. But you readily see that the phosphate going to the lime, the soda must go to the carbonate, sulphate, or hydrate, and you get the same action, the results are always the same, the soda ash being left in solution.

You will notice one thing. They will all explain to you the action on the lime but they do not tell you what becomes of the soda. The man who is selling it does not know; the chemist who got it up does know, but he takes good care that you do not know through any fault of his. When a water is too pure and not satisfied with lime or some proper substance the return condensation or distilled water attacks the iron. The action is termed electrolysis; more commonly speaking, galvanic action. Whenever you add soda to too pure a water so that you have an excess of same over the lime, you then have too pure and an unsatisfied water, which immediately acts as the electrolyte between your poles, giving you the battery connected, and your positive pole, which is always the iron, is destroyed; consequently the pitting, grooving, etc., and general action on the joints and connections takes place.

The only salt of soda that can be successfully used is the tannate of soda and then only when used with four times its weight of tannin. Also with a large excess in weight of sugars, mixing the sugars to handle the sulphates and the tannins to handle the carbonates. These mixtures can be used without any foaming or deleterious action to the iron. It is a subject in organic chemistry all by itself. You can buy these substances at the wholesale drug trade. The reason these soda dopes and soda salts have been used so extensively throughout the country in spite of the fact that the joints are all leaking, steam connections are clamped up with protectors, and the boilers only half clean, is due principally to the user being under the persuasive power of some salesman or man whose business it is to keep the user worked up on theory and talk. But, if an engineer would read chemistry he could figure out the reactions, remembering that there is always a by-product and a main product and when he figures out the main product, he must be sure and figure what becomes of the by-product. When we take, we must give in all chemical reactions. We must take, and, if we do not give, we must produce.

THE MINES LAW OF ONTARIO.*

The Provisions of the Law in Regard to Prospecting and the Acquiring of Mining Locations, Etc.

By Archibald Blue, Toronto.

In Ontario, as in all the older provinces of Canada, the Legislature may exclusively make laws in relation to the management and sale of public lands. The Province is the owner of all unoccupied lands within its boundaries, excepting areas which have been set apart as Indian Reserves; and even on these reserves the title to gold and silver, if not to all ores and minerals, is vested in the Crown as represented by the Executive of the Province.

In the early period of our history mines, minerals, and ores were not deemed worthy of being dealt with by statute law. During the first thirty years all mines of gold, silver, tin, lead, copper, iron, and coal, were reserved to the Crown in the patents, and in the next forty-four years all mines of gold and silver were so reserved. For three-quarters of a century regulations made by Order in Council were the only mining laws. But this was largely owing to the fact that the southern portions of Ontario, which were the first to be occupied, were valuable chiefly for agriculture. It was only when exploration began to be carried northward into the regions of the Archæan rocks around Lake Huron and Lake Superior that evidence began to accumulate of the existence of valuable ores and minerals, and then the importance of making laws to regulate the sale of mining lands and the conduct of the mining industry began to force itself upon the attention of the Legislature. It was known eighty years ago that deposits of iron ore existed in the eastern part of the Province; but the valuable discoveries of minerals south of Lake Huron, Georgian Bay and Lake Nipissing are comparatively modern. Gold, copper, corundum, arsenic, mica, apatite, gypsum and salt occur over a wide area, and some of them in great bodies. Yet, with the single exception of gold, a knowledge of the presence of these minerals in lands occupied by farmers and lumbermen did not weigh a grain in the mind of the Legislature,—no doubt owing to the fact that in most cases the Crown had parted with its interest in the lands. In the western counties, between Lake Huron and Lake Erie, there is an area of about 1,200 square miles underlaid with thick beds of salt, sufficient in amount to supply the world for millions of years; but nearly the whole of this tract of land, with its timber and minerals, was sold to settlers a quarter of a century before the first discovery of salt within its limits. In the eastern counties within the last four years a discovery of corundum was made which has been proved by exploration conducted under Government auspices to have an extent of four hundred square miles. In this instance, however, the lands are mostly in homestead districts, where the minerals are held as the property of the Crown, and they are disposed of under conditions which call for development and the erection and maintenance of works in the Province to manufacture the various products of the ore. But in all its main features the Mines law of Ontario owes its origin and evolution to circumstances connected with the discoveries of minerals in the northern districts—in the territory popularly known as New Ontario.

It is not the purpose of this paper to deal with the subject historically, for this would occupy too much time. It must suffice to describe the law as it is, merely promising that like most other laws, it is a product of experiment, and that no "Finality John" has had part in the shaping of it.

The law is known by its short title as "The Mines Act," and among its first provisions are sections which abolish all royalties upon ores and minerals, and that rescind and make void all reservations of mines, ores and minerals contained in any patent, except patents issued for agricultural lands under the public lands act or the free grants and homestead acts.

Any person, citizen or foreigner, may explore for mines or minerals on any Crown lands, whether surveyed or unsurveyed, except such as may have been withdrawn from sale, location or exploration as being valuable for their pine timber or for any other reason, and any person attempting to explore, occupy or work any lands so withdrawn is liable to a penalty. The main object of this provision is to protect areas which have been sold as timber limits, where the pine is liable to be destroyed by the carelessness of prospectors in building camp fires. Sections which are shown to be rich in ores or minerals may also be withdrawn from sale or lease, pending a careful exploration under the direction of the Commissioner of Crown lands, and the price of lands in a section so proven to be valuable may be fixed at any greater sum than the Act provides, or the lands may be offered for sale at public auction on such terms and conditions as may be fixed by Order in Council.

* Read before the International Mining Congress, June 1900.

When Crown lands are situated within a mining division, and are held and worked under miners' licenses, they are known as mining claims; but when they are situated elsewhere, and are supposed to contain ores or minerals, they may be held or leased as mining lands in blocks or lots called mining locations.

In unsurveyed territory a mining location is required to be rectangular in shape, with the bearings of the outlines due north and south and east and west astronomically, with an area of not less than forty acres, and sides of 20 chains, or with areas which are multiples of forty acres, as 80, 160, 320. In surveyed townships a location may be a fractional part of a lot or section, but so that its area shall be not less than forty acres; and, where road allowances have not been laid out, a reservation of five per cent. of the land is made in the patent, and the Crown or its officers may lay out roads where deemed necessary.

In unsurveyed territory mining locations are required to be surveyed by a licensed surveyor at the cost of the applicants, and to be connected with some known point in previous surveys, or with some other known point or boundary so that the tract may be laid down on the office maps of the territory. The surveyor's plan, field notes and description must be furnished to the Department of Crown Lands within four months of the time of application for the lands, and they will not be regarded as constituting a claim to the location on behalf of the party at whose instance they have been prepared unless they are filed in the department immediately upon completion of the survey. The applicant is required in addition to furnish evidence of the discovery of valuable ore or mineral in the land, as well as evidence of no adverse claim by reason of prior discovery or occupation as far as known to him, and to pay one-fourth of the purchase price or first year's rental within sixty days, and the balance within three months from the date on which his application was filed in the department. The area which any person may acquire in one calendar year of lands containing ores of the same class or kind is limited to 320 acres within a radius of fifteen miles in any one district or county, which may be composed of separate locations of not less than forty acres each; and no firm, syndicate, or incorporated company may acquire more than 640 acres in one year. For every distinct kind of ore discovered within the radius of fifteen miles, the maximum area of land may be taken up in the same year; and so with any discoveries made outside of the radius of fifteen miles. But in case a prospector does not see fit to incur the expense of making a survey of a location and paying the price thereof before he has had an opportunity of proving its value, he may procure from the Commissioner of Crown Lands a miner's license, which will authorize him to stake out and work two mining locations in unsurveyed territory within a radius of fifteen miles, and hold them for a period of two years subject to an expenditure of three dollars per acre in the first year and seven dollars per acre in the second year for actual mining work. If then satisfied that the land is valuable, he may proceed to acquire it in the regular way. In the case of a prospector who is the first discoverer of valuable metals, ores or minerals upon a vein, lode or deposit not less than five miles from the nearest known occurrence of the same kind of metal, ore or mineral, he is entitled to a free grant of one location of forty acres.

Mining lands may be acquired in fee simple upon payment of the price fixed in the Act, or may be taken up under lease tenure subject to the payment of a yearly rental. Both price and rent are regulated by distance from a railway. If a location is in surveyed territory, the price is \$3.50 per acre when within six miles of a railway, \$3 if within twelve miles, and \$2.50 if more than twelve miles from a railway; and prices are 50 cents per acre less in each case if the location is in unsurveyed territory. The rent charge is uniformly \$1 per acre for the first year, 30 cents per acre in subsequent years if the location is within six miles of a railway in surveyed lands, 25 cents if within twelve miles, and 20 cents if more than twelve miles, with a reduction of five cents per acre in each case if the location is in unsurveyed territory. At the end of ten years, if the rent has been paid and the necessary working conditions have been performed, the lessee is entitled to receive a patent for his location free from all conditions, or he may obtain a patent at any time during the demised term upon payment of rent for the full period and performance of all the covenants and conditions of the lease. In practice the lease system provides an easy term of payment, as the aggregate amount at the end of ten years is a mere trifle more than the cash price for a patent. But whether acquired in fee simple or under a lease, a location is held subject to an expenditure for actual mining operations of a sum not less than \$6 per acre during the first seven years immediately following the issue of the patent or lease, whereof \$1 per acre must be expended in the first two years and \$1 per acre in each of the following five years; and if two or more locations are contiguous, the whole of the mining work may be done upon one of them. In default of such expenditure all rights of an owner or lessee are liable to forfeit, and the land is subject to

reversion to the Crown. In the case of lands valuable for iron ore, and where it is reported by an inspector or other officer that a mine may be profitably worked, the owner or lessee may be required to raise 2,000 tons a year for period of ten years, or 20,000 tons in a shorter period of time when the location is not more than forty acres, and a proportional amount if it is more than forty acres, with liability to forfeit of title if this requirement is not complied with. Failure to pay yearly rent subjects a lease to forfeiture, with reversion of the land to the Crown; but in case of co-lessee or co-owner who defaults in rent or performance of working conditions, his interests may be vested in his co-lessees or co-owners who have paid the rent or made the expenditure for working conditions, when delinquency is proven to the satisfaction of the Commissioner.

Pine trees on lands sold as mining locations are reserved to the Crown in the patent, and any person holding a license to cut timber or saw logs on such lands may at all times enter upon the lands and cut and remove such trees, and make all necessary roads for that purpose. The patentee, however, may cut and use trees necessary for building, fencing and fuel on the land, or for any purpose essential to the working of the mines, and may also cut and dispose of all trees required to be removed in clearing the land for cultivation. All pine trees cut on a location except for these purposes are subject to the payment of the same dues as are at the time payable by the holders of licenses to cut timber or saw logs. If a location is held under lease, and in case it is intended to clear any portion of the land for cultivation, the lessee is required to give the holder of the timber license three months' notice, and if at the expiry of that time the timber has not been cut and removed by the holder of the license the lessee may cut and dispose of it, subject to the payment of the same dues as are at the time payable by the holder of the license. Timber other than pine upon a leased location may be cut for building, fencing and fuel, or in the course of clearing for cultivation, or for any purpose essential to the working of the mines; but none shall be cut for any other purpose except with the authority of the Commissioner, and subject to the payment of dues at a rate to be fixed by the Commissioner.

When the surface rights have been granted for agricultural purposes the mining rights may be acquired by a prospector who is the discoverer of ore or mineral thereon at one-half the price or rental of mining lands, subject to compensation for injury or damage to the surface right; and in case the owners of the surface and mining rights cannot agree, the Director of the Bureau of Mines may prescribe the manner in which compensation shall be ascertained and paid or secured.

Whenever the Government of Province sees fit, it may by order in Council set apart any tract of country described in the order as a mining division, and may from time to time add to, diminish or cancel the division by an order. Lands held for mining purposes in such a tract are known as mining claims, and the tenure is one of occupation by any person, partnership or mining company holding a miner's license. Licenses are granted for one year on payment of a fee of \$10, and are renewable from year to year. They authorize the licensee to explore any portion of the mining division, and to mine on any claim marked or staked out by themselves on Crown lands; but any person may be employed by a licensee to work his claim, or he may organize a company to work it, or may transfer it to another licensee. Discovery of a vein, lode or other deposit of ore is prerequisite to the staking out of the claim, and it is deemed to be staked when a discovery post is planted upon an outcropping of ore or mineral in place within the boundaries of the claim, and a stake is planted at each of the four corners, numbered in order from the northeast to the northwest corner. A claim may be a square of fifteen chains, containing 22½ acres, or of any other extent greater or less as may be fixed by regulation, but so as not to exceed a square of 20 chains containing forty acres, and the ground included in each claim is deemed to be bounded under the surface by lines vertical to the horizon. A licensee who has staked out a claim is required within thirty days to register it with the Inspector for the Division by filing under oath an outline sketch of the plan, showing the discovery post and corner posts and their distances from each other, together with a notice in writing setting forth the name of a licensee, the locality of the claim as indicated by some general description, the time when it was marked out, the length of the boundary lines if for any cause they are not regular, the situation of the discovery post and the date of the record; and the Inspector is required forthwith to enter the particulars of the notice in his book, and file the notice and sketch or plan of the claim with the records of his office. If the licensee fails to comply with the requirements for registration, or if having complied with them he or any person on his behalf removes any post for the purpose of changing the boundaries, after the plan and notice have been filed, the claim shall be deemed to be forfeited and all the rights of the licensee in it shall cease. A claim may also be forfeited if the

miner's license has run out and has not been renewed, or if the annual fee has not been prepaid in the case of a licensee who is the holder of more than one claim, or if a sum of \$150 has not been expended upon it in actual mining work. No more than one claim may be staked out upon the same vein, lode or deposit of ore by an individual licensee, unless it is distant at least sixty chains from the nearest known mine, claim or discovery on the same vein or lode; but no licensee may stake out and record in the same mining division more than four claims in one calendar year within a radius of fifteen miles, and for each additional claim after the first a fee of \$10 is required. A licensee who is a holder of five claims or less within a radius of one mile may carry on all mining operations demanded by the Act upon one of them, or different persons holding claims within a radius of one mile may combine to expend all of their operations on one claim for every five claims or less.

When the working conditions have been complied with for a period of four years on a claim of 20 chains square, or for three years on a claim of fifteen chains square or less, or when an equivalent of such working conditions has been complied with in a less period of time, the licensee may apply for and obtain a certificate of full performance of working conditions for the claim free from any further working conditions, renewal fee or miner's license. He may also, if he desires to hold the claim under a patent or lease, proceed to get a survey made of it as a mining location, and pay in the purchase money or first year's rent at the rates fixed by the act for mining locations. This provision, however, is not for the sake of securing a better title, but to satisfy a desire for better description by metes and bounds, a holding under the great seal, and the right to record in the office of the Register of Titles.

Other provisions of the Mines Act relate to mining regulations for the health and safety of men employed in mines and mining works, and for the punishment of offenses against the act. There are also provisions for administration under the office of the Bureau of Mines, which was organized to aid in promoting the mining interests of the Province. The inspection of mines, the conduct of exploratory work under direction of competent geologists, the operation of diamond drills and the encouragement of iron mining by the payment of a bonus to miners for ores smelted in the Province, are all within the sphere of the Bureau's operations.

During the present season ten exploration parties have been organized to make a careful examination and report on the northern regions of the Province. This territory extends from the Quebec boundary on the east to the Manitoba boundary on the west, a length of 700 miles, and its area is about 90,000 square miles, or about 40 per cent. of the whole Province. It is one and a half times larger than the whole State of Wisconsin, and nearly twice as large as the Orange Free State, but excepting along the lines of its canoeable waters it is as little known as the Congo Free State in the heart of Africa. Almost certainly it is a region in which there are great forests of spruce and other kind of trees, valuable for pulp wood; there are wide tracts of clay loam deposited in ancient lake bottoms, as well as large areas of till, both of which are calculated to form the best of farm land; and there are many thousands of square miles of the Archaean formations in which the trained prospector would have every reason to expect to find rich stores of ores and minerals.

I have kept for the close of my paper reference to a new provision of our Mines Act, which, however, has not yet been brought into operation. Its purpose is to secure to Ontario a larger share of an industry which in recent years has been built up out of raw materials which the Province possesses in large abundance, namely the refining of nickel and the production of nickel steel. Two works with ample capital are in course of construction for the production of steel, the refining of nickel and the manufacture of nickel steel, and one if not both of them includes in its scheme a plant for the making of nickel-steel rails for railways, at a cost estimated to exceed but a little the cost of Bessemer rails. For this industry Ontario is well favored by its supplies of the raw materials, and, if deemed necessary for the object in view, effect will be given to the provision of the law when the works are equipped and practically established. Stated in its briefest terms, the provision requires that every person carrying on the business of mining nickel ore in the Province shall pay to the Treasurer of the Province a license fee computed at or below a fixed maximum rate upon the gross quantity of ore raised or won by him during the preceding year, with a right to remission if the ore has been treated in the country so as to yield fine metal, or other form or product of the ore suitable for direct use in the arts without further treatment. But it is provided that until it is brought into force by proclamation of the Lieutenant-Governor in Council, this provision shall not take effect.

EXAMINATION QUESTIONS

For

Mine Managers, Mine Foremen, Fire Bosses, Etc.

EDITED BY J. T. BEARD, C. E., E. M.

Many of the questions given by the several State Boards of Examiners suggest principles which can be more satisfactorily discussed in a separate article than is advisable in an answer to an examination question, which should be as brief and concise as possible. It is the purpose of MINES AND MINERALS, to discuss in this department of "Examination Questions" the principles of practical mining upon which these questions are based, feeling sure that such articles will be appreciated by and be a help to all who are preparing themselves for mine examinations.

Mine Inspectors' Examination for the Sixth Anthracite District of Pennsylvania, Held at Pottsville, Pa., May 8, 1900.

Applicants were allowed from 10 A. M. to 5 P. M., to answer the following questions, constituting the written examination of applicants for the office of Mine Inspector. In addition to the written examination, each applicant was required to pass a subsequent oral examination before they could be recommended by the Examining Board to the Governor for appointment to the office of Mine Inspector.

(a) Name? (b) Age? (c) Are you a citizen of Pennsylvania, and have you been practically connected with the Anthracite mines of Pennsylvania for a period of five years?

QUES. 1.—Give the name and location of the mines in which you have been employed, and the nature of your employment and the length of time you were so employed at each.

QUES. 2.—State what you believe to be the duties of an Inspector of Mines, and show how his time ought to be divided in order to properly perform each of the several duties.

ANS.—This question is fully answered in reply to Ques. 1, page 85, MINES AND MINERALS, September, 1899. See also, answer to Ques. 1, Oral Examination For Mine Inspectors, Iowa, page 86, MINES AND MINERALS, September, 1900.

QUES. 3.—Write a brief but complete description—including the inside and outside improvements, sizes of breaker, hoisting engines, boilers, wire rope, pumps, etc.—of any large colliery with which you are familiar.

ANS.—This question is answered in reply to Ques. 6, page 86, MINES AND MINERALS, September, 1899.

QUES. 4.—Name the gases commonly found in coal mines. Describe each fully.

ANS.—This question is fully answered in reply to Ques. 3, page 85, MINES AND MINERALS, September, 1899. See also, answer to Ques. 9, page 329, MINES AND MINERALS, February, 1900; also answer to Ques. 4, page 428, April, 1900.

QUES. 5.—Describe the several methods of timbering shafts, slopes, gangways, chutes, and headings. State the advantages of each method, and under what conditions of strata you would apply them.

ANS.—*Shafts.*—In firm rock strata little timbering is required, in shaft sinking. Cross buntings of pine, hemlock, or oak (usually, 6" by 8") are employed. These buntings are spaced about six feet apart, and set in hitches cut in the rock. They are firmly wedged in line, from the top to the bottom of the shaft. The buntings furnish a support for the guides, and for the pipes and signal wires required in the shaft, as well as for the partition separating the hoist way from the man or pumpway. In *frail* or *loose material*, shaft lining or curbing is required. The curbing is usually continuous from top to bottom, but at times curbing is only used where the strata require support. (See article "Methods of Shaft Timbering," page 138.)

Slopes, Gangways, and Headings.—The timbering of slopes, gangways, and headings, is fully described in answer to Ques. 39, page 274, MINES AND MINERALS, January, 1900.

Chutes.—The timbering of chutes is very similar to the timbering of slopes, referred to in the previous paragraph. The timbers are usually shorter, and are often set closer together; although this depends very much upon the character of the roof and floor and the permanency of the chute. Where the floor of the chute is laid with iron, cross timbers are introduced to give support to

FIG. 1.

the iron. A line of posts is usually set on one or both sides of the breast, a short distance from the rib, to form the manways *b, b*, Figs. 1 and 2. Sheathing planks are spiked to the inside face of the posts to form the sides of the chute. In some cases the

timbers or posts (*a, a*, Fig. 1), dividing the manway from the chutes are inclined so as to lean against the rib, forming a triangular shaped passageway; such timbers are known as "juglars." These two forms of setting the timbers are shown in Figs. 1 and 2.

QUES. 6.—Describe all the methods used in mining anthracite coal with which you are familiar, and state the varying conditions which make one preferable to another.

ANS.—The methods usually employed in the mining of anthracite coal are the room and pillar, often called the *bord* and pillar, or the pillar and chamber method; the pillar and stall method, and the panel system of mining. In some localities where the cover is not great, the method by stripping is employed. The longwall system of mining has not been successfully employed in anthracite workings, except to a very limited extent. These several systems of working coal are fully described in the article "Systems of Working Coal," page 245, MINES AND MINERALS, January, 1899, and page 292, February, 1899. See also answer to Ques. 5, page 85, MINES AND MINERALS, September, 1899, and also MINES AND MINERALS, March, 1898, page 337.

FIG. 2.

QUES. 7.—State the advantages, if any, of hoisting water in tanks over the usual method of pumping from deep mines.

ANS.—The advantages claimed for hoisting water in tanks as compared with the usual method of pumping are that more water can be handled at less expense by the former method. Also, the difficulties encountered when pumps are employed, in respect to the corrosion of the pump linings and valves by the sulphurous water of the mine, are eliminated, and the annoyance of pipe lines in the shaft and of exhaust steam at the bottom of the shaft, and the necessary attendance upon the pumps are also avoided when tanks are used.

QUES. 8.—Mention the explosives commonly used in mines. Describe their properties and peculiar characteristics, and show their adaptation for certain results in blasting operations.

ANS.—This question is fully answered in reply to Ques. 13, page 139, MINES AND MINERALS, October, 1899.

QUES. 9.—Describe the several systems of extinguishing underground mine fires, and state the conditions under which each could be advantageously used. Give your experience in this branch of work.

ANS.—This question is fully answered in reply to Ques. 8, page 86, MINES AND MINERALS, September, 1899.

QUES. 10.—In a gangway driven in a coal seam ten (10) feet thick, with a bad top and heaving bottom, forty (40) breasts have

FIG. 3.

been worked up a distance of sixty (60) yards, at an angle of sixty degrees, and are standing full of coal, the breasts and pillars are eight (8) yards wide. State how you would proceed to remove the coal and rob the pillars.

ANS.—It is important in this case to keep a manway always open for the escape of the men. The coal in the chutes should not be drawn faster than the work upon the pillars progresses. The safest method to pursue would be to drive a narrow heading up the center of each pillar, which will furnish the escape for the men. Cross-cuts are driven at intervals of say 8 or 10 yards, dividing the pillar into sections; each section of pillar being worked to the rise from these cross-cuts. If the conditions will permit, the pillars may be worked from the upper end downward, the coal being chuted across the manway into the breasts upon either side; but this is not usually practicable. The coal in the breasts is drawn, only as the work progresses. If the pillars are worked from above, cross-cuts will not be required in the pillars, but care will be necessary to keep the manway open for escape. Fig. 3 illustrates some of the methods employed in drawing pillars in steep seams.

QUES. 11.—Describe the precautionary measures you would

adopt to prevent accidents where your gangways were approaching an abandoned mine filled with water.

Ans.—This question is answered in reply to Question 13, page 427, MINES AND MINERALS, April, 1900. See also article, "Precautions Necessary When Mine Entries Are Approaching Abandoned Workings," page 236, MINES AND MINERALS, December, 1899.

Ques. 12.—Make a classification of the accidents occurring in anthracite mines, and state how, in your judgment, they may be diminished.

Ans.—The accidents occurring in anthracite mines are classed under the following general heads, which we give in the order of their relative importance. (1) Accidents from falls of roof or coal. (2) Accidents in connection with the movement of mine cars, machinery, etc. (3) Accidents in connection with blasting, handling of powder, etc. (4) Accidents in connection with mine gases. (5) Accidents in connection with shafts or steep inclines. (6) Miscellaneous. The number of accidents occurring in mines, as classified above, may be very greatly diminished by a strict enforcement of the mining laws. The management and the mine foreman should not only give orders in accordance with the several requirements of the mining laws, but should see that their orders in this respect are carried out. The neglect due to this is the direct cause of a very large number of avoidable accidents. From 40 to 50 per cent. of all accidents in mines are due to falls of roof and these are very largely the result of negligence or carelessness on the part of miners themselves and lack of proper oversight by the management.

Ques. 13.—It is required to raise 800 loaded mine cars daily, in a two-compartment shaft 400 yards deep. Give the general dimensions of the engine, drum, diameter of rope, etc., necessary to properly perform this work, assuming the weight of the load to be $3\frac{1}{2}$ tons, the weight of the car $1\frac{1}{2}$ tons, the weight of cage $1\frac{1}{2}$ tons, and the steam pressure 90 pounds per square inch.

Ans.—Following is the load upon the rope:

Coal	$3\frac{1}{2}$ tons =	6,500 lb.
Car	$1\frac{1}{2}$ tons =	3,000 lb.
Cage	$1\frac{1}{2}$ tons =	2,500 lb.
1" Rope		1,900 lb.
Total		13,900 lb.

Size of Rope.—The gross load or the entire moving load includes the weight of two cars, two cages, one rope, and one load of coal, making a total of 19,400 lb. Assuming the friction of winding to be $\frac{1}{10}$ of the gross load, we have for friction, say 2,000 pounds, which added to the net load gives a total load upon the rope of, say 16,000 pounds. The proper working load for a one-inch plough steel rope is 10 tons. As the working load of a $\frac{7}{8}$ -inch steel rope is $8\frac{1}{2}$ tons, we could use, in this case, such a rope; but on account of the importance of the hoisting rope and the wear to which it is subjected, we prefer to use the one-inch rope, in this instance.

Speed of Hoisting.—Assuming that 800 hoists are made in 10 hours the time of hoisting is obtained as follows:

$$\frac{10 \times 60 \times 60}{800} = 45 \text{ seconds,}$$

for each hoist, including the time required for changing cars, and starting and stopping each trip. Assuming a speed of hoist of 40 feet per second, we have for the actual time of hoisting each load $\frac{1,200}{40} = 30$ seconds. This gives $45 - 30 = 15$ seconds for change of cars, etc.

Speed of hoisting, $40 \times 60 = 2,400$ feet per minute.

Diameter of Drum.—Assuming a direct acting, duplex engine making say, 150 strokes per minute, which gives 75 revolutions of the drum per minute, we have for the diameter of the drum,

$$d = \frac{2,400}{3.1416 \times 75} = 9.96, \text{ say } 10 \text{ ft.}$$

Mean Effective Cylinder Pressure.—Assuming the engine cuts off at $\frac{2}{3}$ stroke, we may calculate the mean effective cylinder pressure from the given boiler pressure (90 lb.), by using the formula,

M. E. P. = $.9[.917(90 + 14.7) - 17] = 71.1$ lb. per sq. in. See "Calculation of Size of a Winding Engine," page 379, MINES AND MINERALS, March, 1900.

Load Upon the Engine.—Assuming that the weight of the car and cage is balanced, since this is a two-compartment shaft, we have for the load upon the engine as follows:

Coal	6,500 lb.
1" Rope	1,900 lb.
Friction	2,000 lb.
Total	10,400 lb.

$$\text{Horsepower, } \frac{10,400 \times 2,400}{33,000} = \text{say } 750 \text{ horsepower.}$$

Size of Engine.—Assuming the ratio of length of stroke to

diameter of the cylinder as 1.4 and the efficiency of the engine as 60%, we have for the diameter of the cylinder,

$$d = \sqrt[3]{\frac{u}{.7854 p r n}} = \sqrt[3]{\frac{750 \times 33,000}{.60 \times .7854 \times 71.1 \times 1.4 \times 150}} = 14 \text{ in.}$$

See page 569, MINES AND MINERALS, July, 1900.

For the length of stroke we have $14 \times 1.4 = \text{say } 20$ inches. The size of engine required for this hoist is therefore $14'' \times 20''$.

Ques. 14.—Describe the instruments used in determining the character and condition of the atmosphere of a mine, and explain how they are used in making such tests.

Ans.—Art. 2, Sec. 6, of the Anthracite Mine Law requires that the Mine Inspector shall provide himself with "The most modern instruments and appliances." He will therefore need the following instruments: watch, anemometer, watergauge, barometer and thermometer. Of these the three first named instruments are important in determining the quantity of air in circulation in the mine, and the ventilating pressure. The last two instruments named are used more particularly in determining the character and condition of the mine air in circulation with respect to pressure and temperature. Another machine known as the Shaw gas tester has been introduced at many of the larger mines, for determining the percentage of gas in the air-current. These instruments and their uses have been previously described. See answer to Ques. 4, page 85, MINES AND MINERALS, September, 1899; Ques. 30, page 273, January, 1900, and Ques. 5, page 86, September, 1900.

Ques. 15.—Describe briefly the geological structure of the Western Middle Anthracite Coal field, comprised within the Sixth Inspection District, giving the names and average thicknesses of the coal beds and the thickness and character of intervening strata.

Ans.—The geological structure of the Western Middle Anthracite Coal field consists of a series of coal beds of varying thickness separated by intervening strata of soft slates, bituminous shales and sandstones. Beginning at the bottom the names of the several coal beds with their average thickness are as follows: Buck Mountain, averaging between 6 and 20 feet in thickness; Seven Foot, averaging from 3 to 7 or 8 feet in thickness; Skidmore, from $2\frac{1}{2}$ to 6 or 8 feet in thickness; Mammoth (sometimes in two or more splits), averaging from 20 to 50 feet where the splits are all joined together; Holmes, from 6 to 10 feet; Four Foot (often considered a split of the Holmes), from 3 to 6 feet; Orchard, from 3 to 7 or 8 feet, and Diamond, from 3 to 10 feet in thickness. The character of the intervening slates, shales and sandstones is usually soft, but the cover rock of the Buck Mountain seam is an extremely hard sandstone.

Ques. 16.—Describe fully the system of ventilation used in any large colliery, giving the sizes of fan and engine, the volume of air circulating, and the number of men employed in the mine.

[In answering this question each applicant would select the colliery with which he was most familiar and describe briefly the system of ventilation employed, stating the sizes of the fan and engine, volume of air passing in the mine, and the number of men employed.]

Ques. 17.—Explain how you would proceed to determine the efficiency of a ventilating fan.

Ans.—To calculate the manometrical efficiency of a ventilating fan, the theoretical water gauge due to the fan's action is first obtained from the formula

$$I = \frac{v^3}{g \cdot 5.2}$$

In which I = the theoretical water gauge (in.); v = velocity of blade tips (ft. per sec.); g = force of gravity (32.16); w = weight of one cubic foot of air (.0766 lb., temp. 60° F., bar. 30"). The efficiency is then determined from the formula

$$K = \frac{i}{I} \times 100,$$

in which K = efficiency of the ventilator; i = actual water gauge (in.).

For example, to find the efficiency of a ventilating fan, 20 feet in diameter, making 70 revolutions per minute, and giving a water gauge of 2 inches, we have

$$I = \left(\frac{3.1416 \times 20 \times 70}{60} \right)^2 \times \frac{.0766}{32.16 \times 5.2} = 2.461 \text{ in.}$$

$$\text{Then, } K = \frac{2}{2.461} \times 100 = 81.27 \text{ per cent.}$$

If it is desired to find the mechanical efficiency (ratio between the effective and theoretical work performed), the usual practice is to take a card from the engine running the fan and calculate therefrom the power employed, and then divide the effective work (qp) in the fan drift by the power employed and multiply the quotient obtained by 100. The result is the percentage of efficiency. This method is faulty, however, inasmuch as it embraces in the efficiency of the fan, that of the engine

and does not present therefore a correct basis of comparison. See article "Determining the Efficiency of a Ventilating Fan," page 137.

Ques. 18.—The volume of air passing through a semi-circular arched tunnel of four (4) feet radius, springing four (4) feet above the floor, is 23,625 cubic feet per minute, what is the velocity per minute?

Ans.—The area of this airway is obtained as follows (See Fig. 4):

$$4 \times 8 + \frac{.7854 \times 8^2}{2} = 57.13 \text{ sq. ft.}$$

Then, to find the velocity, we have $\frac{23,625}{57.13} = 413.5 \text{ ft. per min.}$

Ques. 19.—Under the usual existing conditions, what sized breast pillars would you recommend in mining the Mammoth coal seam, forty (40) feet thick, on the fourth (4th) level, in the Mahanoy Valley?

FIG. 4.

Ans.—This question is to some extent an open one, calling for opinions as guided by experience in different workings of this seam. Under ordinarily good conditions it has been found safe in driving an advance breast in this seam to make the width of the opening 30 feet, and to leave a 40-foot pillar between the openings.

Ques. 20.—State your experience, if any, with electricity applied for both light and power, in coal mining operations; explain its advantages and disadvantages.

Ans.—Among the troublesome features in regard to the application of electricity to mining operations, may be mentioned the following: (1) Incandescence of the conducting wire. (2) Sparking occurring in the motor or caused by a broken circuit. (3) The producing of a voltaic arc between two carbon terminals.

Extensive experiments conducted in Germany in 1897 show the following results:

Incandescent Lamps.—Naked films raised to high incandescence may or may not cause the explosion of firedamp. The breaking of the lamp bulb and the film was usually accompanied by bad sparking which sometimes produced an explosion of the firedamp and sometimes not. In some cases, the filaments remained intact, when the bulb was broken; and in such cases, also explosions sometimes took place and sometimes not. These experiments seemed to indicate that the amperage was the chief element to be considered. Continuous or alternating currents of less than 0.6 ampere did not produce ignition, although sparking often occurred. Stronger currents than this usually caused ignition. The following recommendations are made: Use stout globes with round bulbs, to prevent cracking from water dripping on the hot bulb. Protect bulbs by wire cages. Use low current lamps (0.6 ampere maximum) and high voltage, but not above 150 volts; as excessive volts are dangerous. Do not use lamps with two filaments in series, in order to avoid danger of sparking. Locate leading-in wires far apart, to avoid their being bent together and making a short circuit.

Arc Lamps.—The arc lamp did not ignite coal dust, even in an atmosphere containing 4% of marsh gas; but in 6% of marsh gas explosions took place whether the lamp was already burning or was switched in. Arc lamps, should therefore be condemned for use in coal mines.

Switches, Wires, Etc.—Switches for one or more lamps are dangerous, on account of their tendency to cause sparking. Glowing wires do not cause explosion, although melting wires, especially copper, may ignite the gas; but an iron wire buried in coal dust and heated by the current until it arched strongly did not ignite the coal dust either when it was quiet or when it was stirred into a cloud. Fusing wires protected by a shunt may be considered harmless, but ordinary safety fuses of lead and tin are to be condemned.

Electric Motors.—Large size motors are safer than smaller types, because variations in the load affect them less. Carbon brushes spark less and are therefore to be preferred. In an experiment, a motor placed in a box under a fine wire gauze cover, set fire to the explosive mixture in the box, on starting; but the flame did not strike through the gauze. It is recommended that the motor should be incased in a wire gauze netting and double brushes used. In general, continuous-current motors, switches, fuses, etc. should be avoided, and should be incased wherever they are put up.

French experiments have since corroborated the German experiments mentioned above, and seem to show that an incandescent wire has no power to produce an explosion, except by contact, so long as the wire remains unbroken; but contact with another wire or conductor generally produces an explosion of the firedamp.

Advantages of Electricity in Mining.—Among the advantages of electricity as applied to mining may be mentioned the following: (1) The cost of generation is low. (2) The current is easily conducted to any point of the mine workings; conducting wire is cheap, in comparison with the requirements of other systems. (3) The system is pliable and well adapted to the changing conditions in mine workings. (4) There is less power lost in transmission than in any other system that can be adopted. (5) Electrical apparatus is readily installed. (6) The system not only furnishes power for motor haulage, but also light and power, in the mine workings.

Ques. 21.—A fan attached to the workings of a coal seam eight (8) feet thick, running at the rate of forty (40) revolutions per minute, shows an inch of water gauge. What will be the probable water gauge if the speed of the fan be doubled?

Ans.—The usual rule with respect to the yield and pressure due to a fan, is that the quantity varies as the speed of the fan and the pressure as the square of the speed. According to this rule, if the speed of the fan be doubled the water gauge will be multiplied four times, giving four inches of water gauge in this case. Practically, however, the water gauge obtained will be slightly more than 3 inches. See answer to Ques. 6, page 41, MINES AND MINERALS, August, 1900.

Ques. 22.—Find the area and perimeter of an ellipse whose axes are five (5) feet and ten (10) feet respectively.

Ans.—Area = $.7854 \times 5 \times 10 = 39.27 \text{ sq. ft.}$

$$\text{Perimeter} = 3.1416 \times \frac{5+10}{2} = 23.562 \text{ ft.}$$

Ques. 23.—Explain how you would determine the safe working load for a seasoned hemlock mine prop ten (10) inches square and ten (10) feet long, assuming that the crushing load per square inch is 5,300 pounds.

Ans.—The safe working load in this case is best calculated by the use of what is known as Gordon's formula.

$$P = \frac{fA}{1 + c\left(\frac{l}{d}\right)^2},$$

in which P = the crushing load upon the prop (tons); f = crushing strength of the material (tons per sq. in.); A = smallest area of cross section (sq. in.); c = constant depending upon the material and whether fixed at both ends (for hemlock squared ends $c = .004$); l = length of prop (in.); d = least diameter or thickness (in.). Substituting in this formula the given values, we have

$$P = \frac{2.65 \times 10 \times 10}{1 + .004\left(\frac{10 \times 12}{10}\right)^2} = 168 \text{ tons.}$$

Then using a factor of safety of 4, we have $\frac{168}{4} = 42 \text{ tons, safe load.}$

(See page 77, "The Coal and Metal Miners' Pocket Book.")

Ques. 24.—If a gangway collar six (6) feet long and eight (8) inches in diameter be required to sustain a certain weight, what thickness of collar would be required to sustain a similar weight on a turnout twelve (12) feet wide?

Ans.—Assuming the span of the collar to be 6 feet, in the first case, and 12 feet in the second case; and the cross-section of the collar to be a circle; and since, for the same load, the length of the span varies directly as the cube of the depth of the collar, for beams of circular cross-section; the collar of 12 feet span would require to be $8 \times \sqrt[3]{2} = 8 \times 1.26$, or say 10 inches deep, to support the same load as supported by a collar 8 inches deep having a span 6 feet long.

Examination of Mine Foremen and Hoisting Engineers, Under the New Law in Iowa.

The first examination under the law requiring mine foremen and hoisting engineers to possess certificates of competency was held at Albia, Iowa, beginning August 6th and lasting four days. The schedule called for other examinations to be held each alternate week as follows: Des Moines, beginning Aug. 20, 1900; Oskaloosa, beginning Sept. 3, 1900; Centerville, beginning Sept. 17, 1900; Boone, beginning Oct. 1, 1900. A great interest is being manifested. In the published lists of those taking the examination we notice the names of many who are not holding the positions for which they wish to qualify. This shows a laudable ambition, and argues a healthy, intelligent condition of the miners, as a class, in Iowa. While it cannot but be expected that the operation of the new law will debar some who are now serving as foremen or engineers from holding such positions in the future, yet these vacancies will be quickly filled by those who should in time make more intelligent, practical and useful officials. In this way the purpose of the law is subserved, the

safety of the ten thousand miners in the state is more assured; and in every way the industry of mining is elevated.

At Albion, 43 engineers and upwards of 50 foremen presented themselves for examination, of whom we are glad to say only a very few failed to secure the coveted certificate. Service certificates were also granted by the Examining Board to a large number who produced the "satisfactory evidence" of having performed their respective duties as mine foremen or hoisting engineers for the four years immediately preceding the date of the new law's going into effect, January 1, 1901.

One salutatory effect already observed in this forward march of intelligence is the desire it at once awakens in the mind of all for practical, common sense reading in matters pertaining to mining. And what is true in this respect of the mining industry, is equally true of all trades and professions. It is common to miners, mechanics, and other tradesmen, while they recognize the growing need of knowledge, to postpone its attainment until such knowledge is made obligatory by such a law as passed the Iowa legislature last March.

False Water-Gauge Readings.

The point at which the water gauge reading is taken has a very important bearing upon the results of a fan test. We are accustomed to say that the quantity of air in circulation varies as the square root of the pressure, for the same airway, which means that four times the pressure will produce double the quantity of air in a given airway. We accept this law as a fundamental law of ventilation. It accords with reason, since when twice the quantity of air is passing, in the airway, in a given time, each particle of air moves twice as fast, or meets with twice the number of resisting particles, and strikes each of those resisting particles with twice the force, and from this we conclude that the resistance or pressure head is made $2 \times 2 = 4$ times the original resistance. All fundamental formulas in ventilation are based upon this relation between pressure and velocity, or pressure and quantity, giving us the formula

$$p = \frac{k s v^2}{a} = \frac{k s q^2}{a^3}$$

From the latter of these two expressions, we may write

$$\frac{q^2}{p} = \frac{a^3}{k s}$$

For any given airway, we observe that the ratio

$$\frac{q^2}{p}, \text{ or } \frac{q}{\sqrt{p}}$$

is a constant which we call X . This ratio expresses the resisting power of the airway, and we have called this factor the *potential of the airway* with respect to pressure, or the *pressure potential*. For a constant potential, the quantity of air varies as the square root of the pressure.

But having established this law expressing the relation between the quantity and pressure, we must always bear in mind that the pressure referred to here, is the pressure producing circulation. It is often carelessly assumed by observers, in making fan tests, that the water gauge reading wherever taken, represents the ventilating pressure for that circulation. This is often a very bold assumption, and is a prolific source of error, and has at times given rise to statements to the effect that the law to which we have just referred is not correct, under all conditions. The trouble, however, is not with the law, which expresses a fundamental mechanical principle; but arises from the fact that the water gauge reading, in the position in which it is often observed, does not express the pressure producing circulation. Nor is it possible, in all cases, to obtain a water gauge reading that will correctly express the pressure producing ventilation. This may seem strange to us at first, but a little study will make the matter clear, and will give us a more intelligent idea in regard to conditions that are vital in making a fan test.

We have drawn Fig. 1 to represent a sectional elevation of a mine opened by two shafts, a fan shaft and a hoisting shaft. The lower part of the figure is drawn in plan to show the airway and haulage road extending from the bottom of these shafts, respectively. There is also shown the first cross-cut or breakthrough, between the main intake and return entries. The fan may be either an exhaust or a blow-down fan, but as at present arranged it is the latter. There are two places at which it is common to take the reading of the water gauge in making a fan test; and these are designated by the letters S and U , indicating surface and underground readings, respectively. We must bear in mind that a water gauge reading represents always the *difference* between the pressures upon the two arms of the gauge; and it is true that this *difference of pressure* is the ventilating pressure, at that point of the airway. It does not follow, however, as is too often assumed, that there is no other pressure producing ventila-

tion. In point of fact, there are numerous causes which affect the ventilating pressure or *head of air-column producing ventilation*, which for convenience we will term the *ventilating head*. Some of these causes are positive in their effect and some are negative. Those that are positive act to assist, while those that are negative retard the circulation. It will be more convenient to refer to these several causes as *positive or negative heads*. They may be stated as follows: (1) Head of air-column in shaft, due to a difference of temperature in the upcast and downcast columns. (2) Head of air-column in rise or dip workings, due to difference of temperature between intake and return currents. (3) Damp heads in upcast shaft, due to presence of mine gases. (4) Damp heads in rise and dip workings. (5) Frictional head.

Of the several heads mentioned in the preceding paragraph it will be observed that some are constant heads, with respect to the quantity of air in circulation; that is to say, they do not vary as the square of the quantity or as the ventilating head. Others vary in the same ratio as the ventilating head, and therefore do not affect the results, as far as the relation between the quantity and pressure in any circulation is concerned. All of the heads mentioned, except the frictional head, are constant heads.

To understand clearly how these several factors affect the observations in a fan test, let us suppose the water gauge reading is taken at S . Denoting the atmospheric head by B , and the head due to the action of the fan by p_1 , the pressures upon the respective arms of the water gauge will be $B + p_1$, and B , and the difference of these pressures will be p_1 , which represents the pressure due to the fan's action. Now, suppose that the shafts are deep and have different temperatures, and call the weights of the downcast and upcast air-columns W_1 and W_2 , respectively. If we take a water gauge reading underground at U , the pressure upon the two arms of the water gauge will be

$$B + p_1 + W_1, \text{ and } B + W_2,$$

and denoting by p_2 the head of air-column in the shaft, we have $p_2 = (W_1 - W_2)$. Then, the ventilating head at U is represented by $p_1 + p_2$. If the temperature of the upcast column is greater than that of the downcast, $p_2 = (W_1 - W_2)$ will be positive, and the ventilating head at this point will be greater than the ventilating head at S . If, however, the upcast column is colder than the downcast, or if a blackdamp column exists in the upcast shaft, $p_2 = (W_1 - W_2)$ will be negative, and the ventilating head at U will be less than the ventilating head at S . In the first case the action of the fan, represented by the water gauge reading at S , is *assisted*, and in the other case *retarded* by the head of air-column in the shaft. In like manner the circulation is assisted or

retarded, as the case may be, by the head of air-column often existing in rise and dip workings in the mine, due to the general inclination of the seam. Also, the circulation is either assisted or retarded, as the case may be, by damp heads or columns of blackdamp existing either in the shaft, or rise or dip workings. The most effective of these damp heads are those due to the existence of a large quantity of blackdamp in the return current, pure carbonic acid gas being somewhat more than half again as heavy as air (specific gravity 1.529). This factor has a very powerful influence in retarding the current in deep shafts or seams of steep inclination and which give off considerable blackdamp. When a large quantity of marsh gas is given off at the face of rise workings, ventilation is likewise retarded to a considerable extent, though not to the same extent as in the former case. Marsh gas given off in considerable quantity at the face of dip workings, or blackdamp in rise workings, operates to assist circulation. All of these heads are constant heads acting to assist or retard the ventilating current. The frictional head referred to always acts to retard circulation, but this head has no effect to change the ratio between the quantity of air in circulation and the pressure producing this quantity, since it varies in a like manner, or as the square of the quantity.

To properly conduct a fan test the water gauge should be

placed at both *S* and *U*. When the fan is stopped momentarily the water gauge at *S* will fall to zero, while the water gauge at *U* will indicate by its reading the influence of any columns that may exist in the shaft either as positive or negative in effect. A few minutes of time should be allowed to elapse, however, before the reading at *U* is taken, in order that conditions may adjust themselves. Whatever columns may exist in the rise and dip workings of the mine should be estimated by taking the average temperature of the intake and return of the airways, and observing their condition with reference to the amount and kinds of gases they contain. This last estimation will necessarily only be approximate. In flat seams or seams of small inclination, inside air-columns may be ignored; but in steep seams, they should always be estimated as closely as possible both with respect to temperature and gaseous condition.

The reading of the water gauge at *S* will express correctly the pressure due to the action of the fan, while the reading at *U* will express correctly the pressure producing ventilation in the mine workings in flat seams or seams of small inclination. In steep seams the reading of the water gauge at *U* must be corrected from the observations explained in the previous paragraph. The reading at *U* for flat seams, or the corrected reading for inclined seams, will vary with the square of the quantity of air in circulation, in accordance with the law that the pressure producing ventilation varies as the square of the quantity of air in circulation. The reading at *S* will not vary according to this law when there is any considerable air-column either positive or negative in the shaft or the workings, since the shaft column is constant for the same atmospheric conditions.

The reading at *S*, however, will vary approximately according to the square of the revolutions of the fan. We say approximately, because the fan has not the same efficiency at all speeds, its efficiency increasing as the speed decreases. The existence of any considerable air columns in the shaft or in the mine will have the effect to vary considerably the efficiency of the fan. For example, where these air columns are positive, assisting ventilation, a larger quantity of air will be drawn through the fan than that due to the fan's action, and as a result a larger proportion of work will be absorbed within the ventilator. On the other hand, the fan will be rendered more efficient seemingly, when the existing air columns are negative, or retard ventilation, since a smaller quantity of air will traverse the fan, a portion of the pressure due to the fan's action being neutralized by these negative columns.

To show the disproportion arising from the constant heads, either positive or negative, existing in shafts or in rise or dip workings, we will assume a particular case. Suppose before starting a fan the water gauge reading at *U* is .5'', and indicates a positive air column that will assist the action of the fan; and suppose further, when the fan is started and run at, say, 50 revolutions per minute, the water gauge at *S* reads 2''. The ventilating pressure is then $2 + .5 = 2.5''$. If now, the fan is speeded up to 100 revolutions per minute, the water gauge reading at *S* would increase to $(\frac{100}{50})^2 \times 2 = 8''$, supposing the efficiency of the fan to remain constant. This is in accordance with the accepted theory that the quantity of air in circulation varies as the speed of the fan, and the pressure varies as the square of the quantity or as the square of the speed. In practice, however, the quantity varies in a ratio somewhat less than the speed of the fan, and the pressure varies accordingly. Thus, it accords more nearly with the results of practice when we say the quantity varies as the fifth root of the fourth power of the speed ($\sqrt[4]{V^4}$), and the pressure as the square of this ratio. If this be correct, when we double the speed of the fan we will obtain $\sqrt[4]{2^4} = 1.74$ times the quantity, and $\sqrt[4]{2^4}^2 = 3.04$ times the pressure.

For the present purpose, however, assuming the efficiency of the fan to be constant, and the quantity to vary as the speed, and the pressure as the square of the speed, we have 2'' w. g. at 50 revolutions, and 8'' w. g. at 100 revolutions. The ventilating pressure in each case being $2 + .5 = 2.5''$, and $8 + .5 = 8.5''$.

The ventilating pressure is thus increased $\frac{8.5}{2.5} = 3.4$ times, instead of 4 times, as would be indicated by the water gauge at *S*, if this were the only gauge in use.

If the air column in the shaft is negative and acts to retard ventilation, the ventilating pressure increases from $2 - .5 = 1.5$ to $8 - .5 = 7.5$ or $\frac{7.5}{1.5} = 5$ times. In other words, when we have doubled the speed of the fan, in the case, we obtain only 3.4 times the ventilating pressure when the ventilation is assisted by the constant air columns, but when it is retarded by these columns we obtain 5 times the pressure. From these facts it will be observed that the water gauge reading at *S* must always be used to show the true variation of pressure due to the fan's action alone, while

the water gauge at *U*, for flat seams, and the corrected water gauge at *U* for inclined seams, must be employed to show the correct variation of the pressure producing ventilation.

Determining the Efficiency of a Ventilating Fan.

The testing of a fan to be used for ventilating purposes is a matter of prime importance. In the choice of a fan, one of the first questions that we ask is in regard to its efficiency, and we are often surprised when we are told that a certain fan presents an efficiency of 70, 80, or even 90 per cent. We accept this statement with a certain seasoning of salt, as we are familiar with numerous fans that are doing satisfactory work, and that have efficiencies varying from 50 to 60 per cent. Indeed, we have seen statements to the effect that the efficiency of certain types of ventilating fans cannot rise above 50 per cent. These facts together with observations made upon fans in actual practice, cause us to regard with considerable doubt the statement that a fan has an efficiency of between 80 and 90 per cent.

The real reason for these varying statements may be attributed largely to a conflict of terms. There are several meanings for the term efficiency. The term always refers to a ratio between theoretical and practical results. For example, an engine may show by calculation based upon its size, type, valves, etc., that it is capable of developing one hundred horsepower. In a test, the indicated horsepower of this engine as obtained from the engine card, may fall short of this amount, and may equal only, say 65 horsepower. We then say that the engine has an efficiency of 65 per cent., meaning that the effective horsepower, or the horsepower available for moving a given load, is 65 per cent. of the calculated or theoretical horsepower, the balance being absorbed in the engine.

The term efficiency as applied to a fan, is complicated by numerous misunderstandings. In some cases it is taken to mean the ratio between the actual and the theoretical pressure which the fan will develop; while in other cases, the term refers to the ratio between the actual and theoretical power. In conducting a test to ascertain the efficiency of a fan, the mistake is usually made of including the efficiency of the engine employed to drive the ventilator. A card is taken from the engine driving the fan, and the power estimated from this card. This method, of course, includes the power consumed in running the engine. The mistake would not be so bad in effect, if the efficiency of the engine varied as the efficiency of the fan; but this is not the case, inasmuch as the efficiency of an engine is usually greater as the speed is increased, while that of the fan decreases as the speed increases.

There are other causes which render the results of fan tests unreliable and extremely variable. These are the methods of measuring the velocity of the air-current or the quantity of air in circulation, and the ventilating pressure; the neglect to observe the temperature of the air at the point where the velocity and pressure are measured, and the barometric pressure. Whatever increases or decreases the density of the air affects the work of the fan and its efficiency as a ventilating motor. It is therefore important in making any true fan test that the velocity, pressure, and temperature of the air should be taken at a point in the airway or fan drift not too far removed from the fan, but at a sufficient distance to avoid the oscillations incident to its action. The size of the airway at the point where these observations are made, should be carefully measured and its area computed. While taking the observations, care should be used not to allow the body of the observer to decrease the area of the airway, as the velocity of the air-current will be much too high, if this is the case. Another precaution necessary in measuring the velocity of an air-current with the anemometer, is to move the anemometer to different positions in the airway so as to secure an average reading. It is well known that the velocity of the current is greatest at the center of an air-course and much less as we approach the perimeter, where the air is rubbing along the sides, top and bottom of the airway, and is retarded. A reading taken in the center will be too high, while a reading taken near the side will be too low. Another precaution to be observed occurs when there is a tendency of the air to flow along one side of the air-course. This is the case when the airway is curved or changes its direction; or the same effect may be produced by some obstruction in the airway, which too frequently escapes the notice of the observer. Quite frequently it occurs that the anemometer used is unreliable and does not indicate correctly the velocity of the air-current. The instrument should be tested, from time to time, by comparison with other instruments. Its accuracy may also be proven by the powder or flash test, but this should be carefully made.

Still another source of error by no means unimportant although very common, is the neglect to allow for natural air-columns existing in the shaft, or in rise or dip workings. Since this is a grave error it will be explained in a separate article upon

"False Water-Gauge Readings." The reading of the water gauge in all such cases should be corrected to give only the pressure due to the action of the fan. Too often, the total pressure producing ventilation is assumed to be the pressure due to the fan or ventilator, which may be the case in some instances, but in the majority of cases this total pressure does not correctly express the pressure due to the ventilator.

Manometrical Efficiency.—We have referred to the fact that the term efficiency as used at different times and by different persons, relates to different ratios, it sometimes being understood to mean the efficiency between the actual and theoretical pressures, while at other times it is taken to mean the ratio between the actual and theoretical powers. The term *manometrical efficiency* has always the former significance. The actual pressure is obtained from the reading of the water gauge, while the theoretical pressure is calculated from a formula based upon the assumption that the theoretical head due to the action of the centrifugal ventilator is one-half of the theoretical head due to the tangential velocity of the blade tips. The formula expressing the theoretical water gauge due to a ventilator is,

$$I = \frac{v^2}{g} \times \frac{12 \times 1.2}{1,000}$$

In which I = theoretical water gauge (inches); v = tangential velocity of blade tips (feet per second); g = force of gravity (32.16); $\frac{1.2}{1,000}$ = approximate ratio of density of air to density of water; 12 is a factor reducing the head of the air-column from feet to inches.

To obtain the manometrical efficiency we use the formula

$$K = \frac{i}{I} \times 100.$$

In which K = efficiency (per cent.); i = water gauge due to the action of the ventilator.

EXAMPLE.—The water gauge reading taken from the fan drift at the top of the shaft is 2 inches. The fan is a 10-foot fan, making 160 revolutions per minute. Determine the manometrical efficiency of the fan.

$$\text{SOLUTION— } d = \frac{3.1416 \times 10 \times 160}{60} = 83.78 \text{ ft. per sec.}$$

$$I = \frac{83.78^2}{32.16} \times \frac{1.2 \times 12}{1,000} = 3.14.$$

$$K = \frac{2}{3.14} \times 100 = 63.6 \text{ per cent.}$$

Mechanical Efficiency.—This term refers to the ratio between the actual and theoretical powers. By the actual power is here meant only that portion of the power producing ventilation that is due to the action of the ventilator, as the term actual pressure, used above, applies only to that portion of the pressure producing ventilation, which is likewise due to the ventilator. The mechanical efficiency would be consistently calculated from a formula giving the theoretical work performed by the ventilator. The difficulty is, however, to obtain an expression for this work that is applicable to all machines under all conditions. The fan formulas proposed by M. Murgue have not been found of sufficient utility to base the calculation of the work upon them. The chief objection to these formulas lies in the fact that they are given in terms that are not sufficiently tangible and are not readily comprehended. They do not show the influence of the breadth of the fan blade upon the yield, or the effect of atmospheric conditions; they do not discriminate between a small fan running at a high speed or a larger fan running at a lower speed, except in the matter of the equivalent orifice of the fan. This last factor especially, has been so little understood, in making many fan tests as to have led to much confusion and error.

In view of these facts, it has come to be common practice to base the mechanical efficiency of a fan, upon the indicated horsepower of the engine as obtained from the engine card, instead of upon a theoretical formula. This practice has given rise to other errors, to which we have previously referred; namely, the including of the efficiency of the engine in the efficiency of the ventilator. The question that interests all users of power is, What per cent. of the power applied is made useful, in performing any allotted work? Practice does not concern itself with the question as to whether any given formula or expression is correct; but, if 100 horsepower is applied to the driving belt or to the crank shaft of a fan, what percentage of this power becomes effective upon the air, in the use of different types of fans? This is the practical question. Scientific investigation will continue to analyze formulas, in the interest of correct machine designing, but the practical test will always be that referred to above, to ascertain the ratio between the effective power and the power applied to the fan shaft.

We would suggest when the engine card is used as a basis for

finding the efficiency of a fan, that the following method be employed: (1) Run the engine at several fixed speeds with the belt thrown off, or with no load upon the engine, and take engine cards at each given speed. (2) Run the engine at the same fixed speeds as before, under the load induced by the revolution of the fan, and take engine cards for each given speed, under this load. Calculate the total work in each respective case, deducting the work of running the engine under no load from the work performed at the same speed, when the fan is in operation. The difference will be the power applied to the fan shaft for each respective speed. This work would not naturally agree with the work expressed by a formula, inasmuch as the work absorbed by the mechanical revolution of the fan has not been deducted; but practice would usually prefer that this should not be taken out. In other words, from a practical standpoint the efficiency of the ventilator should preferably include the power necessary to revolve the ventilator. From a scientific standpoint, as far as the formula goes, it would be desirable to eliminate the work performed in the mechanical revolution of the ventilator. This can readily be accomplished by taking the first set of engine cards at the same fixed speeds when the fan is in operation, but the resistance of the mine has been cut off by suitably arranging the doors in the fan drift and casing. By this means, the difference of work as calculated from the two sets of engine cards, at each respective speed, will represent the actual work performed upon the air, at each speed, and should correspond to the work indicated by the expression Qp . There may not, however, be complete correspondence, inasmuch as the methods at hand for measuring the velocity and pressures of air-currents are to a considerable extent crude.

Methods of Shaft Timbering.

The amount of timbering employed in lining a shaft depends wholly upon the character of the strata passed through. Where the strata are self-supporting, that is to say, do not tend to chip or break off and fall into the shaft, the shaft lining is usually omitted; cross-buntings only being used to furnish the necessary support for the cage guides and for the lines of pipe, signal wires, etc. usually carried down the shaft.

The character of the strata will change very materially as sinking progresses. After passing through the surface soil, or drift, as it is called, there is usually encountered a hard-pan of clay or other rock material; or there may be a sub-stratum of gravel or quicksand at this point, with a hard pan below it. The strata of the coal measures are especially variable, and alternate from soft to hard and *vice versa*, quite often in the course of sinking. Test bore holes at the location of the shaft have usually made known this character before the operation of sinking has been commenced.

In the sinking of deep shafts the manner of lining the shaft is often changed to conform to the character of the strata at any point of the sinking. Shaft lining is, of course, employed at all points where the strata are not self-supporting, and is carried down until a hard stratum is reached of sufficient thickness to warrant the abandoning of the shaft lining. Cross buntings are then used while passing through the harder strata and lining again introduced if softer strata are encountered below. When this is done arrangements must be made for the handling of the water coming from the strata above the hard pan, either by the laying of a water tight curb, or building a coffer dam as described later, and conducting the flow of water above this point down the shaft in pipes. In the sinking of shallow shafts it is not customary to abandon the shaft lining when a hard stratum of a few feet in thickness is reached. In general, the lining of shallow shafts is made continuous from top to bottom, where lining at all is required.

Water and Quicksands.—In shaft sinking in a synclinal basin, the existence of an impervious stratum or hard-pan is usually heralded by a considerably increased flow of water. According to the character of the surrounding country, the flow of water encountered may have a considerable head. As long as the character of the strata is such as to render them quite firm and self-supporting, the water these strata contain will cause little trouble until nearing a hard-pan or stratum that is impervious to the flow of water. At this point the water accumulates, and when dammed back may exert considerable pressure. When there is a sub-stratum of sand immediately overlying the hard pan, the worst conditions in sinking are realized; especially, if the thickness of the sand is considerable. Such a stratum is known as a *quicksand*. A quicksand of some thickness, at a considerable depth below the surface, presents some of the most troublesome features encountered in shaft sinking. The sand flows with the water as a fine hard-grained silt that cuts the linings and valves of the pumps used to drain the water from the shaft. This flow of sand in the water that is being pumped gradually undermines

the overlying strata, often causing a settlement that may injure the shaft lining. For this reason it is important in passing through a stratum of quicksand, to choke its flow behind the shaft lining as much as possible. This has been accomplished at times by means of alternating thicknesses of shaft curbing, so arranged as to present a corrugated or uneven surface at the back of the lining, or against the sand. This is shown in Fig. 1, where alternating layers of 2"×8" and 2"×10" plank are used. The result of this is that the flow of water and sand running down behind the curbing tends to choke itself. This arrangement of the curbing has always produced a marked effect upon the amount of flow, both of sand and of water.

FIG. 1. TIMBERING TO KEEP BACK WATER AND SAND.

In passing through a free quicksand it is often necessary to keep the curbing well down to the bottom of the excavation, as shown in Fig. 2. The work must be accomplished rapidly. When the thickness of the sand is not great, or the stratum lies

FIG. 2. BOTTOM SUPPORTS.

at a shallow depth below the surface, it may be passed through safely in the manner shown in Fig. 2. When, however, a quicksand lying at a greater depth and of considerable thickness is encountered, other apparatus (see Fig. 4) will be required. An iron shoe or muf, fitting the outside of the shaft curbing, as shown in Fig. 4, is often employed at the bottom of the shaft, in such cases. The shoe or muf is carried down in advance of the curbing by excavating the sand from beneath it. When this is done the jacks shown in Fig. 2, are made to rest upon cross timbers supported by the shoe. These jacks are used to force the shoe downward, while they act also to support the curbing above.

At times when the flow of sand is quite free, short sheathing piles or spiles are used as shown in Fig. 2, to temporarily choke the flow of the sand. These spiles are driven through the curbing between the sets, as shown. They are often used in this manner when the curbing has parted; but great care must be taken to give

FIG. 3. JOINTS.

support to the curbing below, as the use of the spiles throws additional weight upon it. Indeed, their use has often proved an evil in the end, although they always provide a temporary relief.

It often happens in sinking through quicksand or when the shaft has nearly reached a stratum of quicksand, that the sand boils. An outburst frequently occurs in the bottom of the shaft,

under such conditions, that overwhelms the sinkers before they are able to escape. At such times, the sand and water sometimes rise to a great height in the shaft, and remain for a while, when they will again subside. This boiling of the bottom of a shaft forms one of the most dangerous features in connection with sinking.

Swinging of the Shaft Curbing.—One of the results of sinking through quicksand of any considerable depth is the tendency of the shaft curbing to swing out of line, or to twist, as the case may be. When this takes place it usually results in the enforced abandonment of the shaft, except where the shaft is circular, or the excavation is larger than is required in the completed shaft. To avoid such an occurrence the shaft curbing, under such conditions, is often secured by dropping sets of rods from the surface, and tying up the curbing in sections to prevent its sinking. This method is illustrated in Fig. 4. Cross-buntings are introduced at intervals of 8 or 10 feet, and the vertical rods passed through these cross-buntings, which in turn carry the curbing. To prevent, as far as possible, the swinging of the shaft, an additional system of diagonal bracing is sometimes carried down the shaft.

Framing of Shaft Timbers.—In the framing of shaft timbers several forms of joints are used. Regard must always be had to the expense of framing as well as to the efficiency of the joint for resisting pressure, and the ease with which the timbers may be inserted. Several of these forms of joint used in lining shafts are shown in Fig. 3. The simplest form of joint is that shown at A, Fig. 3. In this form, there is no framing required; the alternating sets are arranged to break joints, as shown in the figure, and a triangular corner piece is spiked firmly from top to bottom of the shaft. This forms a very efficient and cheap method of curbing shallow shafts. The form of curbing shown at B, is adapted to heavier pressures and deeper shafts. The form of joint shown at C, is a very cheap and efficient joint, used in passing through particularly loose strata where difficulty is often found in placing the sets. Each alternate set is arranged to break joint. At D is shown the same form of framing as is employed at C, but the timbers are not arranged in complete sets, the shorter lengths being always sprung into and supporting the longer timbers. This method is not often employed, as it does not furnish sufficient protection against side pressure upon the short lengths. The form of joint shown at E, is more expensive, although a very efficient joint. At F is shown the manner of alternating layers of thin plank while passing through quicksand or running strata. The planks are spiked upward from below, as they are inserted.

Thickness of Shaft Curbing.—Where the strata are self-supporting, 4-inch planks set upon edge, form a very good shaft lining to the depth of 50 or 75 yards. A lining of 3-inch plank has often been used with good results to a depth of 40 or 50 yards, in firm strata. Where a considerable flow of water is encountered and a coffer dam is built to dam back the water, the thickness of the curbing must be very much increased. In such cases, the following formula may be employed to determine the thickness of white pine curbing which will resist a given head of water.

FIG. 4. BOTTOM SHOE.

$$t = .016 s \sqrt{d},$$

in which t = thickness of curbing (inches); s = clear, unsupported span of curb timber (inches); d = depth below the surface (feet). This formula, however, makes known the worst case that could occur, when the water obtains a head at the surface of the shaft, and is not to be employed ordinarily.

Wedging Curb.—What is termed a *wedging curb* applies more particularly to a circular shaft. It is a curb made in segments, to be laid upon an off-set or shelf cut in a hard stratum, and afterward wedged firmly in place to form a suitable foundation for the curbing above. A water-tight joint is made at this point, by

packing the space behind the wedging curb very tightly with moss. Wedging curbs, strictly so-called, are not employed in sinking a rectangular shaft, but in their place is often used a curb of heavy timbers laid in cement upon a shelf of hard rock. This curb furnishes a foundation for the construction of a coffer dam, which is simply a tight shaft lining of heavy timbers, laid with a tar-felt joint to exclude the water. Sometimes the timbers forming the coffer dam are mortised together to provide a water-tight joint. It is important to leave weep holes, or to provide for the drainage behind the shaft curbing at this point, by suitable pipes that will conduct the water to the bottom of the shaft. In some cases, there is excavated in the hard pan behind the shaft curbing, a sump of sufficient size to hold the water that accumulates, and to locate at this point a pump for raising the water to the surface. By this means, there is a considerable saving of power by not allowing the water to drain to the bottom of the shaft. In this arrangement, it is usually necessary to excavate a small manway entirely surrounding the shaft. The excavation should be well timbered.

[Very complete descriptions of shaft timbering in different sections of the country will also be found in MINES AND MINERALS for Sept. 1898, page 49, and June 1900, page 481, and page 103 of the present number.]

A New Design for a Compound Duplex Pressure Pump.

The illustration shows a compound duplex pressure pump, designed to develop a maximum pressure of 700 lbs. per sq. in. The liquid end is of the end-packed trombone style; the cylinders are made of special metal, and mounted thereupon are separate chambers for the location of the valves; these chambers are also constructed of special metal and are designed with a view of facilitating quick access for the inspection of the valves.

The valves are of the hydraulic pattern, made of steel, and guided from below. An extension piece is provided for supporting the water plunger, and an approved adjustment device provided therefor.

The water end is mounted on heavy supporting columns. An engine of the transposed cylinder type is furnished, giving

SMITH-VAILE COMPOUND DUPLEX PRESSURE PUMP. POT VALVE STYLE.

free access to all steam pistons without dismantling the pump. The outside valve adjustment is a feature of this design.

One of these pumps was recently installed and is now in use by the El Paso & Northeastern Railway Co. at the Summer resort of Cloudercroft N. M., a beautiful resort in the Sacramento Mountains, situated over 8,700 feet above the sea level, and reached from El Paso, Texas, via the E. P. & N. Railway "Cloud Climbing Route." The pump is used to furnish the entire water supply for the resort and also for railway company's tank use. It pumps the water from a distance of three miles and to an altitude of 600 feet. During the past summer the pump has been supplying the town of Cloudercroft, having a population of from 1,200 to 1,500 people, with its entire water supply, and the railway company with its water tank supply. However, the pump has not been worked to anything near its capacity and the railway company now contemplates using the superfluous water for the purpose of making a lake.

Further particulars regarding this style of pump may be obtained by addressing the manufacturers, the Stilwell-Bierce & Smith-Vaile Co., 287 Lehman Street, Dayton, Ohio, U. S. A.

According to Prof. Borchers, the eminent electrometallurgist, the world-manufacture of calcium carbide is utilizing a power equal to 180,000 horsepower; that of the alkalies and the combinations of chlorine, 56,000 horsepower; of aluminum, 27,000 horsepower; of copper, 11,000 horsepower; of carborundum, 2,600 horsepower; of gold, 455 horsepower.

Some Placer Mining Notes and Wrinkles.

Written for MINES AND MINERALS, by Prof. Arthur Lakes.

In endeavoring to locate old river channels remember that water is a lazy fellow and will try to seek for its course the easiest way and the place of least resistance. It is therefore apt to work the easiest and softest ground first till it is all used up, and then it reaches the hard steep rock bank and stays there. Hence old river channels in a broad placer river valley are not infrequently found hugging the hardest and steepest rock bank.

For natural rock riffles, naturally catching and arresting the gold, much depends upon the way the bed rock strata, such as slates or shales, dip. If they dip down stream, with edges tilted up stream, they catch the gold, but if the strata dip up stream, the water with the gold flows over them, and the sand and gold are apt to glide over the edges of the strata and not deposit until some other obstruction is met.

In the case of potholes, which to the novice would seem most attractive places for gold deposit, it is a curious fact that these are generally disappointing; the waterfall and churning water which hollowed it out seem to have washed the smooth pothole quite clean of whatever gold may have temporarily been deposited in it. It has been observed that if the bank above the pothole descends steeply, the pothole is liable to be empty of gold, and the gold it may once have held may be found farther down on the rim. If there is a sliding surface from the pothole down stream the gold is liable to be caught not far below the pothole especially in bed rock dipping down stream.

In hydraulic mining, in two pipes or nozzles, one wide the other narrow, the big pipe will carry more cannon-ball like force or volume, and do more general damage along a placer bank; the narrow one will shoot more like a rifle and its damage be confined to a small area. For far shooting all depends on compressing the water power within narrow limits. A two inch nozzle will shoot farthest, but a four inch nozzle will do most damage.

A pipe under pressure of only 35 ft. head might throw 60 feet, whilst the same with 300 feet head, would throw water a far greater distance.

A flume may get choked by too great and sudden a rush of water and material.

Blasting large boulders in a placer is often found cheaper than moving them by cranes, or other means. Blasting of this kind is commonly done by laying a stick of dynamite on a boulder of average size, covering it with loam and then firing it.

In beginning to work, or develop a new placer ground, work up stream from below.

Grading for the flumes may be up to eight inches in twelve feet. Supposing an obstacle occurs in the flume, temporarily choking it, instead of tackling it at the exact point, where the obstruction is, go below it and clear the down stream end of the obstruction. An obstruction is liable to occur at change of grade in a flume from 6 inches to 4 inches.

A giant nozzle often cuts down rather than undermines a bank, and drives material before it to the flume; this is in shallow banks; in deep banks under-mining is necessary, of course.

It is not well to put a giant too near to the mouth of a flume, or the volume of the water and debris flying before it would be liable to choke the flume. If the giant throws water about 60 ft. it should be located at least 120 ft. from the mouth of the receiving flume. The flume cutting ditch may cut back a canyon to the bank 20 to 50 ft. long, and 20 to 30 ft. deep in a day. A bank may be undermined by the nozzles in a sidelong manner, as well as by directing the water against it point blank. Men digging up bed rock throw it as well as the gravel into the flume to go over the riffles. The flume is built onwards as the banks are cut farther back. A powerful head or powerful water pressure is the great thing needed in hydraulic mining. As there is a great deal of noise around a hydraulic placer signals are made by a whistle, or by movements of the arms. The main difficulties to be overcome in a flat placer, like in an open meadow with a not too rapid stream going through it, is to dispose of the debris, or detritus. Placers of this kind are apt to get choked with their own debris, unless means are available for removing it.

For original contributions upon mining or metallurgical topics descriptive of new and handy devices and appliances we will pay at the rate of five dollars (\$5) per column, payment to be in technical or scientific books to be chosen by the contributor.

By S. J. Routledge, Ensley, Ala.

The slope was 2,700 feet long and the profile is shown in the figure.

Diagram of a road profile showing a 6% dip, a 4% dip, a 3% dip, and a 5% dip. The road is 1500 ft long and has a 1200 ft section with a 5% dip. The road is labeled "Engine" and "Pin pulled here".

It took only 3 men and 1 mule to operate the tail rope, one man on the rear of the front trip and one man on the front of the rear trip, one mule to pull the empties down, and one driver. Before we put our rope in operation we were only getting 200 tons with 6 mules from this part of the mine but after we got the rope in and the men acquainted with their work we averaged 790 tons. We have been using the tail rope for seven years and are still running it to get coal from this part of the mine.

In March, 1900, 282 stones were found 250 miles up the Mazaruni River. They were sent to London, where they were examined and the lot valued at \$12 per carat. Recently 400 small stones were brought down from the same locality. They were washed out by nine men in eighteen days by very crude methods. The stones are octohedron, varying in weight from a decimal of a grain to a carat and a half in the crude state. London dealers

By Frank H. Mason, United States Consul General at Berlin.

It is plain that, with all progress which has hitherto been made in steam-engine practice through higher pressures, superheated steam, economical cut-offs, or successive cylinders, there is always an important and inevitable loss of heat energy when the steam, having done its work, is discharged into the open air or changed back to water by contact with cold water in a condenser. When the exhaust is into the open air, the steam has

Digitized by Google

without corroding them. Their demonstrations, although not practically conclusive, were so promising that Professor Josse, as a technical authority on this subject, took up the problem, and, after several months of highly satisfactory laboratory experiment, caused to be constructed and connected with an ordinary working steam engine of the compound type an additional condenser and auxiliary engine, the power of which could be exactly measured. The whole working apparatus is shown in the figure herewith submitted, and the technical details will be explained by the drawing, and may be thus described:

Referring to the diagram, in which dimensions are given in millimeters, h and n represent the high- and low-pressure cylinders of an ordinary compound steam engine, with a stroke of 19.69 inches and a speed of 41.5 revolutions per minute. From the low-pressure cylinder n the exhaust steam passes into the surface condenser, called in the diagram the "vaporizer." In this vaporizer, or condenser, the cooling medium used, instead of water, is liquid sulphurous acid (H_2SO_3), which has a boiling point so low that it is immediately decomposed by the heat of the exhaust steam, whereby the sulphur dioxide gas (SO_2) is liberated, which passes over into the cylinder of the auxiliary engine S , where its work is done as in an ordinary steam engine. The auxiliary cylinder has a diameter of 12 inches; and a stroke of 19.69 inches, with a speed of 77 revolutions per minute.

After passing through this cylinder, the sulphurous vapor enters the surface condenser, around the tubes of which cold water flows as in an ordinary steam plant. Here the sulphurous vapor is condensed to liquid and is forced by the pump back into the vaporizer, where it begins its cycle again, the same SO_2 being used over and over again indefinitely. There are, therefore, in fact, two condensers, the first serving, as it were, as a boiler or steam generator for the auxiliary engine; and this boiler, instead of being fired by coal, obtains all its heat from the exhaust steam from the engine, and, instead of converting water into steam, evaporates a liquid which is much more volatile—i. e., has a far lower boiling point.

In the long series of recorded tests with the plant shown in the figure, the following results were attained:

The steam engine is of the compound type, of good modern construction, and, being given a steady load, developed 34 indicated horsepower, with a consumption of 18.96 pounds of steam per indicated horsepower hour. The auxiliary machine working with the sulphurous vapor indicated 19 horsepower—that is, an increase of 56 per cent. and yielding, instead of 1 horsepower, 1.56 horsepower for the same steam consumption and reducing the steam consumption from 18.96 to 12.13 pounds per indicated horsepower.

The experiments showed on the average that for every 33.169 pounds of steam passing through the main engine 1 horsepower could be gained in the auxiliary machine. Applied, therefore, to an ordinary single-cylinder steam engine, exhausting into the air at high temperature, the percentage of power saved by this new device would be very much higher than the economy reached in these experiments, which, as has been shown, were made with a highly improved compound engine. From the average of these experiments, it may be broadly stated that, given a fairly economical compound engine, using 16.5 pounds of steam per indicated horsepower hour, half an indicated horsepower could be produced in the auxiliary machine for every indicated horsepower developed in the main engine. Assuming an average vacuum of 23.62 inches, corresponding to a temperature of 140° F., the saving of heat must be accomplished by using a liquid which can be vaporized to a high pressure at or below that temperature. Assuming, further, the upper and lower limits of temperature within which the operation is confined to be 140° and 67° F., the pressure of the sulphurous vapor would range from 10.05 down to 2.35 atmospheres above open-air pressure. A working pressure as high as ordinary steam-boiler pressure is therefore readily obtained at a comparatively moderate temperature. Moreover, the volume of sulphurous-acid vapor necessary to contain the number of heat units corresponding to the work to be performed is much smaller than the volume of steam which would be required for the same purpose. As the saving to be effected by the auxiliary engine depends directly upon the difference between the highest and lowest temperatures involved, the greatest gain will therefore be made either when the water in the surface condenser is as cold as possible or when the heat of the exhaust steam from the engine is at a maximum, as is the case with a single-cylinder steam engine without condenser, which may be anywhere up to 212° F.

The expense of this improvement is practically all in the construction cost of the vaporizer, condenser, and auxiliary engine itself, and its economy may be realized from the fact that the exhaust steam from a 2,000-horsepower central-station engine should furnish power to drive an additional 1,000-horsepower engine, which can be connected as an extra cylinder to the steam

engine or run independently, and thus increase by 50 per cent. the power developed without adding a pound to the quantity of fuel consumed. When, in view of the present coal famine throughout Europe, it is remembered that the steam-engine energy of Germany alone, afloat and ashore, is not less than 3,717,264 horsepower, the commercial importance of such an improvement will be readily apparent.

A New Water Purifying System.

It is generally known that even a small accumulation of scale will greatly increase the fuel and repair bills, reduce the capacity and efficiency of the plant and cause the burning out of boiler tubes. In some districts this scale proves so troublesome that it is difficult to keep a plant in operation without frequent interruptions for the purpose of cleaning and repairing the boilers and replacing the tubes. Most up-to-date superintendents have long been figuring on the installation of some system which would remove all scale-forming ingredients before the water reaches the boiler. The Tweeddale system as described by the Chicago Boiler Cleaner Co. is based upon the principle that all foreign substances whether held in solution or suspension can be released by electrical and chemical action, and precipitated to the bottom of the tank, whence they are easily drawn off.

The apparatus itself consists of a pair of tanks which hold a water supply sufficient for six hours' run. In the bottom of each tank is located an aerater and oxidizer combined. This device contains a system of metallic plates filled in with coke, which sets up a chemical or galvanic action in the water.

A strong jet of air is forced through the oxidizer and aerater pipes producing an agitation and aeration which combined with the electrical action and chemical reagents cause first a thorough mixture of all the contents of the tank, and then a releasing of the impurities held by the water. At the proper juncture a small quantity of a standardized reagent is injected, and when the disturbance ceases the water unites with the base of the reagent forming a coagulated mixture which seizes upon the released impurities and, acting as a filter, carries them down to the bottom of the tank by ordinary precipitation at the rate of about 12 ft. per hour.

No mechanical filter is required. Any filtering apparatus must not only be expensive to install and refill, but almost impossible to thoroughly clean. The only filter employed is that which forms in the water itself, and carries the released impurities to the bottom of the tank by ordinary sedimentation.

At the end of this process water which was cloudy and muddy before is said to become clear as crystal, so that a pin at the bottom of a ten foot tank is visible to the naked eye. Not only is it claimed that the water is clarified but it is also purified and softened so that it becomes palatable to the taste and delightful to the touch. The purified water is drawn from the surface by floating pipe connections, while precipitated impurities are carried away by waste pipes located at the bottom of the tank. While one tank is being treated as described above the water supply is taken from the companion tank. The whole process is amazingly simple, effective and economical, and apparatus and reagents employed are quickly understood and easily handled by the ordinary engineer. Water treated by this process will under no circumstances produce scale formation in boilers. Not only this, but the elimination of scale-forming ingredients will soften and eventually remove whatever scale has already formed.

This system eliminates what is perhaps the most disagreeable and expensive feature of steam production, and easily pays for itself in the increased efficiency and economy of the plant.

The manufacturers are prepared to install a complete purifying plant for any responsible firm with the understanding that if it does not meet their requirements and do exactly as claimed it will be removed free of charge. For further particulars, plans, specifications, blue prints, etc., address the Chicago Boiler Cleaner Company, 321 Dearborn St., Chicago, Ill.

In a letter to *The Times*, Sir W. B. Richmond, president of the Smoke Abatement Society, states that there are about 18 million tons of coal consumed annually in London, costing some 16 millions sterling, of which probably 3 million tons are consumed by gas and other manufactories. About two-thirds of the heat produced by the combustion of coal is lost in the ordinary grates by passing up the chimneys, and the loss thus incurred is about 8 millions sterling a year. It has been proved beyond dispute that factory furnaces can be quite easily rendered smokeless, and at a saving to their owners of from 10 to 20 per cent. of the fuel consumed. With the use of the automatic feeder far cheaper coal than anthracite can be adopted. The technical committee of the Coal Smoke Abatement Society has examined and approved grates which, while they maintain the open fire, consume all the carbon, and hence no appreciable quantity of smoke ascends the chimney.

NEW INVENTIONS.

EDITED BY H. M. LANE, M. E.

Complete specifications and drawings for any of the following patents can be obtained from the COMMISSIONER OF PATENTS, WASHINGTON, D. C., at the following rates:

Single copies.....	5 cents each.
Copies by subclasses.....	3 cents each.
Copies by classes.....	2 cents each.
An entire set of patents.....	1 cent each.

MEANS FOR CONCENTRATING ORES ANHYDROUSLY.

No. 655,496. SAMUEL MARION, PHILADELPHIA, PA. *Patented Aug. 7, 1900.* This invention provides for concentrating ore or sand containing valuable metal without the use of water. A drum *A* is rotated

upon the shaft *B*, and has an inlet closed by the door *a'*. Within the drum, a fixed discharge-chute *C* is so arranged that material dropped on it gravitates through the spoked outlet *A* to the discharge-hopper *C'*. The inner periphery of the drum *A* has wings *a*, which, in accordance with the direction of rotation of the drum, serve merely to agitate the material contained therein, or to pocket certain portions and deliver the same to the chute *C*. The operation of the apparatus is as follows: The drum is partially filled and is then rotated in the direction indicated by the arrow *P*, the wings *a* stirring the material so that the heavier particles gravitate to the bottom. The drum is next rotated in the opposite direction, as indicated by the arrow *O* with the result that the wings *a*, encountering the tailings *Y* pocket and carry them through the mass, beneath the valuable concentrate *Z*, and deliver the worthless material upon the chute *C*.

MINE-CAR BRAKE.

No. 653,722. HOPKINS J. WILLIAMS AND RACHEL MORGAN, NANTICOK, PA. *Patented July 17, 1900.* Journaled to the sills and intermediate to the wheels is a rock-shaft *4*, each end of which projects a slight distance beyond its bearings, and is preferably formed angular and provided with a removable casting *5*. Arms *6* are bolted in sockets in the casting and extend a short distance therefrom. A bail-shaped lever *8* is pivotally secured to the sides of the sills. A short link *10* is

pivotally secured to each side of the lever a short distance from its pivotal point and also to the outer end of the arm *6* upon that side of the car. The lever can be formed in any suitable manner, although it is preferred to bend each of the side pieces inwardly to form a lip *11*, to which is bolted a cross-piece *12*, which is grasped by the attendant and forced downwardly when it is desired to apply the brake.

The brake-shoes *13* are pivotally secured at their upper ends to the inner side of the sills. Each of the shoes is connected with the rock-shaft *4* by means of a link *14*, which is pivotally secured to the shoe at one end by means of a projection and secured at its opposite end to a

short arm, which projects from the shaft *4*. The arms at each end of the rock-shaft project in diametrically-opposite directions, so that the links from the shoes upon the opposite sides of the lever can be secured to said arms in such manner that the oscillation or rocking of the shaft will simultaneously move the brake-shoes toward or from the wheels. By constructing the parts in this manner the arms and links virtually

form the two members of a toggle-joint by means of which the pressure or force exerted by the compound-lever movements above described will be correspondingly increased, thus making the improved brake very effective in controlling the movement of the car, which is a very material consideration when the weight of the contents of the car is taken into consideration, which is frequently a ton or more, which must be wholly controlled by pressure applied to wheels of exceedingly small diameter. The same apparatus may be easily worked by a foot brake arranged as shown.

COKE-BREAKER.

No. 655,162. PHILLIP F. POORBAUGH, OF ALLEGHENY, PA., ASSIGNOR TO THE PITTSBURGH COAL MINE SUPPLY COMPANY, OF PENNSYLVANIA. *Patented July 31, 1900.* A rectangular frame is provided at one end with a triangular casing *2*, with a shoulder *3* at the bottom. The upper end

of the breaking-plate *5*, is secured by a cleat *4* while the lower end is normally supported by the shoulder *3*. This plate contains teeth bolted in place as shown. The body portion of these teeth is hexagonal and the teeth taper to a point at one end. The plate *5* at a point near its lower end has a bent portion *10*, the upper face of which is at an angle to the upper face of the remaining upper face of the lower part of the plate, as by such construction the upper row of teeth in the plate *5* is upon substantially the same relative plane as the teeth in the drum at the time each row of the latter teeth is about to pass between the upper row of teeth in the plate *5*. *6'* is a flange arranged at each side of the teeth *6* forming a fixed cutting-tooth at the sides of the plate. Each end of the hub of the revolving cylinder is provided with an annular offset, forming a shoulder *13*, which surrounds one end of the fixed bearing *19*. Near the inner end of *19* is a groove *20* to catch the dirt or dust and prevent the same entering between the joint of the shaft-bearing and hub. *23* is a dust-preventing flanged collar. The drum is suitably arranged to receive teeth which are of the same construction and secured in the same manner as the teeth for the breaking-plate. The drum-teeth are so arranged that when the drum is operated they will pass between the teeth of the plate and when in such position will be on the same plane as the teeth *6*.

COAL-SEPARATOR.

No. 655,580. JOHN R. RICHARDSON, OF SCRANTON, PA. *Patented August 7, 1900.* The coal enters the upper end of the chute and passes down the incline *A* to a more abrupt incline or dip *B*, made by a series of bars *a*, in the form of a grating that connects the inclines *A* and *C*. The spaces between the grate-bars are sufficient to permit of the passage of slate and culm and refuse of this nature. The coal and refuse coming down the incline are agitated by a rotary agitator *D*. This is composed of a shaft journaled in the side walls of the chute and a series of disks *b*, mutilated at opposite points by having quarter-sections cut out, leaving spaces. The disks are separated by spaces *d*, providing for the discharge of the culm and slate. These spaces are preferably wider than the spaces

between the grate-bars, and in order to prevent clogging the disks *b* are made with grooved peripheries, adapted to closely fit the corresponding edges of the grate-bars, as shown at *f*. As the edges of the disks *b* project above the level of the upper incline *A*, the coal and refuse bank against it; but as the agitator is rotated the cut-out portions form pockets

into which the coal and refuse drop, the slate and culm passing through the spaces between the disks and the grate-bars. In the rotation of the agitator the contents of the pocket remaining is carried over and discharged upon the incline *C*. At the bottom of this incline there is a second grating *E*, its bars being given the form of a swell, and the end of the incline extends to an opening through which passes more of the refuse. As the mass slides up over the bent grate-bars *E* some of the refuse which may have passed the agitator and first grating passes through and the clean coal bounds upwardly by reason of the shape of the grating *E* and is caught by an overchute located above the main chute and directly in line with the swell or curve of the grating *E*.

GOLD-SAVING APPARATUS.

No. 652,900. R. H. POSTLETHWAITE, SAN FRANCISCO, CAL. *Patented July 3, 1900.* This invention relates to a special form of apparatus for recovering the gold from ore, tailings or placer material and is intended

for use principally in connection with the dredge. The general arrangement can be understood by referring to the accompanying drawings in which *A'* represents an inclined trommel driven by any suitable mechanism, such as gearing. The material is introduced at the end only and subjected to the screening action of the trommel and to streams of wash water through the pipe *B*. The fine material escapes through the screen and drops into the distributing trough *B'* or the inclined screen *C*, the latter being intended for more evenly distributing the material in the trough *B'*. It will be noticed that the trough *B'*

inclines toward each side, but that the highest point is not placed in the middle. The object of this is that as the trommel travels in the direction indicated by the arrows the major portion of the material passing through the trommel will be thrown to the right and hence a smaller distributing box can be employed on that side and still equalize the amount fed to each trough. Any coarse material is distributed through the chute *A'*. On each side of the distributing box *B'* are placed tables *C'* which are covered with blanket or other fibrous material, held in place by means of a layer of expanded metal, which is firmly clamped on top of the fibrous material. A pocket *D* is arranged across the tables to act as a riffle and has a mercury well for collecting values. The flow of the material through the different tables is controlled by valves which regulate the openings *b*. The discharge from the ends of the table *C'* is received by the inclined trough *D'* and carried to the head of the machine where it is allowed to flow into the discharge or tailing trough *D''*. This trough is also provided with riffles in order to save any material which has escaped the tables above. The whole plant is intended to be erected upon the floor of a dredge, as *A*.

MINERAL-SCREEN.

No. 655,160. PHILLIP F. POORBAUGH, OF ALLEGHENY, PA., ASSIGNOR TO THE PITTSBURGH COAL MINE SUPPLY COMPANY, OF PENNSYLVANIA. *Patented July 31, 1900.* The rectangular frame is arranged at an inclination, and power is applied to revolve the shaft *2*, carrying cams *6*, *6'* thus elevating the screen *10* ins. by the contact of the cams *6* with the anti-friction-rollers *20*. This elevating of the screen-shoe discontinues when the smallest portion of the cam is reached, and the screen then falls upon the bumper *21*. This movement of the screen-shoe will cause the material to travel rapidly, as well as screening the same. During the fall of the end of the screen-shoe the oil contained in the hollow shaft *19* will be forced up through openings and lubricate the anti-friction-rollers. The inclination of the screen can be increased or diminished by the adjustment of nuts and if desired the fall or the lowering of the screen-shoe can be done more rapidly, by increasing the tension of a spring placed alongside of the frame of the screen by means of the nut *17*.

COAL MINES AT STREATOR.

An Interesting Description of the Important Coal Fields and Mines in La Salle County, Illinois.

Surface and Geologic Conditions—Plants of Chicago, Wilmington and Vermilion Coal Company—Electric Haulage—Star Coal Company's Mines and Methods—Rope Haulage.

Written for MINES AND MINERALS, by A. Dinsmore.

La Salle County on the northern edge of the great Illinois coal field, has a varied surface and is rich in mineral wealth. The Illinois River with its level now raised two feet by the waters of the Chicago Drainage Canal, divides it almost centrally. The Fox, Big and Little Vermilion Rivers, besides a number of smaller streams, all join the Illinois and make the drainage unusual for prairie land. High rocky bluffs and deep gorges along the Illinois, as well as the undulating surface, both north and south of this river, to the very border of the county, differentiate it sharply from any adjoining.

Coal underlies nearly the whole area, four seams, known as geologic numbers 2, 4, 5, and 7 all being represented, with an aggregate thickness of 16 feet. The great uplift which brought the oldest rocks in the state, the magnesian limestone of the Lower Silurian, to the surface at Utica, lifted the coal measures 400 feet, so that they overlie unconformably this limestone as well as the St. Peter's sandstone.

Of these seams of coal, the remarkable one is No. 7. It extends from this the northern part of the state, almost to its southern end, being found in Williamson County from seven to ten feet thick and outcropping on the Ohio River. The special economic qualities of this coal are a low percentage of fixed carbon and a correspondingly high percentage of volatile constituents, rendering it of notable value for steam making and domestic use. It was chiefly from this seam that more than 1,000,000 tons were mined last year in and about Streator.

This busy town is situated in the southern part of La Salle

County, on the high bluffs of the Big Vermilion River, whose yellow bed and water indicate the origin of its name.

The largest operator here is the Chicago, Wilmington and Vermilion Coal Company which is now working two shafts. No. 1 is about four miles from Streator at the suburb of Heenanville. This mine is worked by the three entry room-and-pillar system. It offers many features of interest, some of these due to its situation. The shaft is 92 feet deep and the coal runs out into four ravines. Entries have been worked out in these, so that now there are these natural escapes for the men, beside the air shaft which the law requires. The mules walk out of the mine through one of these escapes to their pasture at night. Here I may mention that another luxury connected with mining at this shaft is the special railway train of comfortable cars which takes the men from Streator to their work in the morning and carries them home promptly at 3:30 in the afternoon.

The land in the vicinity of the mine is so high that the water needed for the boilers, accumulates by drainage from the surrounding farms, in a pond near the shaft. The white oak used for timbering grows in the immediate neighborhood.

The seam of coal averages 8 feet in thickness, 2½ feet of this in places seem to belong to No. 5 rather than to No. 7; the two seams are usually together, but sometimes have half an inch of slate between them. The blasting is mostly "from the solid" with powder, the shots being fired at the noon hour and when the men leave for the day. Last year 5,754 kegs of powder were used. The coal comes out in blocks so large that often it is all

that two men can do to load one of them on the cars. These cars carry 3,500 pounds of "run of mine."

The coal is separated by a Link-Belt shaker screen into "lump," "nut," and "screenings," 40 per cent. being screenings. These are now taken from the screen to a building 250 feet away to be cleaned by the Illinois Coal Washing Company. The coal is carried on a sprocket chain 500 feet long with "flights" 18 inches apart to bins placed over 4 Forrester jig washers. These stand side by side at a height of 40 feet above the ground. The washers are built of wood. A wooden plunger mixes the coal and water as they fall together into the washer. The coal, owing to its light specific gravity, passes on the top of the water into a trough below the washer, while the slate and soapstone refuse fall below into a

SHAFT NO. 2, STAR COAL CO., KANGLEY, ILL.

Copyright 1900, by The Colliery Engineer Co.

bin. As the washed coal is taken on another sprocket chain from the troughs, fresh water falls in a number of jets upon it, to rinse it. Then it is carried to the draining piles at the top of the building, whence it falls into cars ready for shipment. The capacity of each washer is 150 tons in 8 hours. Ten men are employed in operating the four washers.

The mine has been worked for 6 years, and somewhat more than 200 acres of coal have been taken out. The average day's

PLAN OF NO. 2 MINE, STAR COAL CO., KANGLEY, ILL.

work of the 370 miners now employed in not quite 4 tons per man. The miners represent several nationalities; a large number are Slavs from Russia and the Balkan States. This may explain the fact that the beautiful Greek church which was a part of the Russian exhibit at the world's fair in Chicago, is now in Streator.

At the Chicago, Wilmington and Vermilion Company's Shaft No. 2, mining seems to be carried on with the minimum of hard labor and the maximum of comfort and safety, so far as old time conditions are concerned. Electricity has largely taken the place of oil lamps and of both man and mule power.

"The mine," to quote its manager, Mr. Keating, "is shaped like a shoestring." Furthermore, it is at very different levels in different parts. The workings dip 20 feet in 600 in one section and 12 feet in the same distance in another. In the steepest place, the grade rises one foot in nine feet. The mine is worked both north and south from the shaft. The north side falls 21 feet in the first 600; then for the next 600 feet it rises until it is 31 feet above the bottom. Then it dips, till it is only 5 feet above the bottom; 700 feet east, it falls 5 feet below the bottom. Besides all these changes of level, a sandbar from 50 to 170 feet wide divides the mine into two parts. This is probably the bed of an ancient river. It is tunneled to connect the two sections of the mine.

In such a mine, haulage was necessarily a very serious problem, now successfully solved however by electricity. Two electric motors, one at the north and one at the south working are flying back and forth between the shaft and the ends of the main entries, each making the round trip of more than a mile in from 7 to 9 minutes and drawing 14 loaded cars of coal at a time. These motors are made by the Goodman Manufacturing Company, of Chicago. Their motion is so steady and the track is so well constructed that the cars are loaded two or three feet above the top. The motors run with a trolley attachment, the overhead wire being placed not between the tracks, but over the one next the wall. The approach of a train, especially from a point near a declivity, is a strange spectacle: on such a down grade, sand is sprinkled on the rails to increase the friction and the wasted electricity streams up in flames from 2 to 3 feet high, as if to herald this noisy, terrifying monster rushing out of the far gloom. I say *gloom*, because though the main entries are strung with electric lights they are not luminous or powerful enough to relieve the distant darkness.

Only two men are required to manage the long electric train, one riding on the motor, and the other on the rear car. These men are taken from the ranks of the miners.

The main entries are so high that the wires do not endanger a man of ordinary height, and are wide enough to allow for another track beside the trolley tracks. On this the men generally walk and the mules travel at night when taking in timber. The haulage in the side entries which are 7 feet wide, is entirely by mules.

This mine, like all the No. 7 seams is worked by the room-and-pillar system. It is 116 feet deep at the shaft; the coal is about 6 feet thick. The roof is of rather fissile soapstone which is specially likely to break when the weather is warm; great care is taken to prevent accidents from the falling laminae.

A good deal of water has to be bailed out of the mine. This is done by four men who lift it in buckets into a water car in which it is hauled to one of 3 sumps; from them it is pumped by an electric pump on the south side of the mine. An electric pump is now being put in place at the north side. But the water has yet to be lifted to the top. This is done by a Wells pump of 26 inch steam cylinder and 18 inch water cylinder, and a Blake pump of 24 inch steam and 12 inch water cylinder. The water cannot be used in the boilers, which are supplied from the Streator mains only two miles distant.

The capacity of the pit cars of which I have said, 14 are drawn at once by the electric motor to the shaft, is 3,500 pounds. In these the coal is lifted to the top of the shaft by the hoisting engine, and there falls into a hopper. The contrivance for opening the cars is worth noting. Their ends are on hinges; a hook suspended from a timber in proper position, catches a strap on the end of the car as it comes to the top landing, opening it automatically as the car tips, and thus the contents are emptied into the hopper, from which they fall upon a Link-Belt shaker screen, to be separated as at the other mine. Some of the slack is carried over to that shaft to be washed. The weighing is done as the coal falls into the hopper, by means of a Fairbanks Morse & Co's automatic quick-weighing attachment.

The air in the main entries of this mine seems as fresh as in the open. A fan 10 feet in diameter is revolving 160 times a minute at the top of the air shaft.

The power for the whole plant is furnished by 5 boilers each of 66 h. p. capacity. The dynamos of 600 amperes capacity were built by the old Sperry Company, and are run by an Ide engine, made in Springfield, Illinois.

The output of this mine is now about 1,200 tons a day, taken out by 390 miners. The total tonnage last year was 329,069 tons, against 372,433 tons at Shaft No. 1.

A description of this company's new and finely equipped mine in geological formation, No. 2, at South Wilmington, Grundy

SHAFT NO. 2, CHICAGO, WILMINGTON AND VERMILION COAL CO., STREATOR, ILL.

County was published in "MINES AND MINERALS," in October, 1899. The name of the flourishing town that has grown up near that shaft has lately been changed to Lawton.

The Star Coal Company is second only to the Chicago, Wilmington and Vermilion in the extent of its operations at Streator. It has been mining since 1877 and has worked out four mines. At present it is running four mines at Carbon Hill, in Grundy County, in No. 2 seam, and has just put down a new shaft to the

same vein 210 feet from the surface, at Kangley, four miles northwest of Streator. No coal has as yet been taken out here, for being in No. 2 seam it must be a "longwall" mine, and miners who work by this system are not now to be had in this locality. But only a few yards from this shaft is the company's No. 2 mine which is in operation. Nothing could be more convenient than its situation, for the station, Kangley, on the Chicago, Burlington and Quincy R. R. is but a few feet from the mine. The property has lately been improved by having a new air shaft at its north workings and by a connection with an old shaft at the west. From one natural escape where the coal has been taken out to the surface, the men walk out and eat their dinner under the trees.

The feature of special interest in the working of this mine is the rope haulage in the main entries. This endless rope runs at the rate of 3 miles an hour by power from an engine at the bottom, directly under the boiler room. To this engine, the steam goes down through a drill hole 60 feet from the shaft. The rope requires no attention when once it has been started by the pumpman in the morning until noon; then it is oiled and runs on till quitting time. The company has just put in 8,000 feet of new steel cable of $\frac{7}{8}$ inch diameter. It is composed of 19 wires to the strand and has 6 strands. Experience has proved that fine wire wears better than coarse. The rope is wound on an iron drum and also upon a Walker wheel in front of the engine, and three feet from the drum. This system of haulage in addition to mules in the side entries, is necessitated by the shape, size, and irregularities of surface in the mine. It is 86 feet deep and worked by the two entry system. In the 14 years since it was opened 500 acres of coal have been taken out. A sandbar 160 feet wide in places, has

THE "DOWN TOWN" MINES

Of Leadville—An Account of Their Development and the Changing of Leadville From a Silver to a Gold Mining Camp.

Written for MINES AND MINERALS, by Prof. Arthur Lakes.

We remember some years ago camping on the site of the present Leadville, and starting a deer not far from the location of some of the afterwards noted mines. Placer mining was going on then in "California Gulch" but that was all the mining there was. "Heavy rock" thrown out of the placers as a nuisance proved to be carbonate of lead. It was quickly traced to the ledges whence it came.

A few months after we paid a second visit. Leadville or the "Carbonate Camp" was then born. Prospectors by hundreds and thousands were scattered over the hills, and men were hurrying here and there with boards over their backs rigging up the first shanties of the young town.

Later we visited the Camp a third time as a member of the U. S. Geological Survey, when Messrs. Emmons, Cross, and Jacobs were engaged in unraveling the complicated geology of the region with its wonderful intrusions of porphyry and its numerous and profound faults; a very necessary work to aid the miner in his locations and mining operations.

Again, years after, we visited Leadville to find it had changed with depth from a superficial carbonate ore camp to a sulphide one. It was still, however, emphatically a silver-lead camp, though it had changed from carbonates to sulphides.

We paid a short visit after the slump in silver, and found on

THE "DOWN TOWN" MINES, LEADVILLE.—1, Penrose; 2, Star; 3, Bohn; 4, Bon Air.

been tunneled. In this pieces of timber of such size were found as to indicate that it was once the bed of a river. "When the miners struck the sandbar, water flew like cider from a barrel," said the superintendent. This great volume of water was disposed of by digging a ditch for its escape.

Four boilers furnish the power for the haulage and hoisting engine, the belt pump and the fan. The water used in them comes from Spring Lake a mile and a half away.

No. 7 vein averages in this mine from $5\frac{1}{2}$ to 6 feet in thickness, though in places it measures 12 feet. The present output is 500 tons a day. The entire output for the year ending July 1899 was 149,137 tons.

For the same year the Acme Company and William Howe and Co. both operating at Streator, produced respectively 86,166 tons and 55,686 tons, from the No. 7 seam. Besides these, there are about a dozen other private companies mining here in the same seam, using horse or hand power, and doing a team trade.

For the information and very courteous attention received at Streator while visiting the mines, I wish to express my acknowledgments to Mr. W. S. Cherry, Superintendent of the Chicago, Wilmington and Vermilion Company, and to his mine managers Mr. Robert Jordan and former State Mine Inspector James A. Keating, also to Mr. C. H. Rathbun Superintendent of the Star Coal Company.

The contract for pumping the water from the Comstock mine has been completed and the water has been lowered 386 feet below the Sutro tunnel. The Evans system of pumping which was used is said to have worked very satisfactorily.

the southeast end that a portion of the Leadville district had accommodated itself to existing financial circumstances and needs by changing into a gold-belt camp. The "Little Johnny" or "Ibex" had found at a certain horizon very nearly coincident with the silver belt that a zone of oxidized porphyry carried an extraordinary amount of free gold, as well as sulphides containing gold, and borings as well as shafts were being put down over that area in search of the continuity of the gold-bearing zone.

And now again, recently, we have visited the far-famed camp, our object being mainly to see and study what have been called the "down town" mines.

For a long period of Leadville's history mining operations were confined more or less to the Mosquito Range, east of, or back of the town, which covered some square miles along the flatter portion at the base of the hills, and upon the moraine mesas extending down from the "Mosquito Range" into the broad Arkansas Valley. But few mines transgressed from the hills into this "down town" portion. The U. S. Geological Survey maps showed that there was a probability of ore bodies existing in the strata even under the very streets of the town, and several so-called "down town" shafts were put down; the experiment proved successful, and the ore bodies, as well as the ore-bearing strata, were found continuous beneath the city, but with the ore was found also a vast amount of water. The success of some of these "down town" undertakings led to the question as to how far to the westward or underneath the broad Arkansas Valley, hitherto condemned as sterile, the ore-bearing strata might extend. Could it underlie the valley generally, or was its continuance from the Mosquito Range abruptly terminated by a fault such as the most westerly or Carbonate fault? Or, again,

if the strata did once continue westward even to the base of the opposite Sawatch Range had it not all been scored away by the great glacier that once occupied the Arkansas Valley, and might not its place on the top of the underlying granite have been replaced by the heavy and deep morainal matter which the glacier dropped on its retreat and melting? As the whole valley was a plain entirely and deeply covered by morainal drift there was no way to solve this question except by practical experiment by shafting and boring.

From a theoretical geological point of view we have reason to believe that the ore-bearing strata now forming the Mosquito Range once extended to the base of the Sawatch Range. We know that from Cambrian to Carboniferous times the ancient seas laid down strata from the Colorado or Front Range, now forming the eastern rim of South Park, to the Sawatch Range, which was then a huge granite island in the Paleozoic Ocean, that these strata, whilst at first lying horizontal, were penetrated by intrusive sheets of porphyry bringing metallic matter with them, and that later the shore-line strata with thin included porphyries were folded up into the range called now the Mosquito, and in process of folding were severely faulted by a series of step faults more or less parallel with the trend of the range. Subsequent erosion and glaciation left the country in the condition of today. Seeing that the Sawatch was evidently the western shore line of this Paleozoic sea it is remarkable that we do not find any sedimentary strata resting on or upon its flanks. We can only account for this on the hypothesis either that such strata were scored away by the Arkansas glacier, or that the eroded stubs of it are deeply buried along the flanks of the Sawatch Range, or that by some later movement of the range a profound fault along its flanks has carried such strata down out of sight.

To the north of the town of Leadville two miles, we find the Cambrian quartzite outcropping along the South Arkansas River at a considerable distance west from the Mosquito Range, showing its farthest extension so far as at present known into the Arkansas Valley. Resting on the top of this Cambrian quartzite is a thickness of about 500 feet of material which may all be drift matter or it may contain other members of the Paleozoic series, such as the ore-bearing Carboniferous limestone; this has to be proved by shafting or boring. This is the only clue and proof of western extension of the ore-bearing strata we have to the north; the interval of several miles to the south towards the city gives absolutely no clue, all is apparently surface drift. To the south, in the vicinity of Malta, we have granite, and at the town of Granite this rock outcrops boldly and unmistakably with no sedimentary rocks resting on it. The interest there now centers in taking the Carbonate fault as our absolute eastern limit, and from it creeping gradually by a series of experimental shafts and boring out into the Arkansas Valley, and finding out tentatively whether the ore-bearing strata exists below it and how far westward it extends.

To prove this important point which may result in nearly doubling the mining area of Leadville, and so doubling the size and value of the town, has occupied for a long time the energies and enterprise of Major A. V. Bohn in face of the ridicule of many, and even of the grave opinions of those well competent to form an opinion. He was convinced that the ore-bearing strata extended beyond or to the west of the Carbonate fault, which by geologists and general consensus had been determined as the greatest possible western limit. He put down shafts himself and interested others in his project to put down more, the result has been that ore bodies and strata have been found in full force for a considerable distance west of the Carbonate fault limit, and it is only now a problem how far west these successes may extend, a question which is a most attractive one for future experiment.

The first start in testing Mr. Bohn's views was by him on the Lucy B. Hussey shaft of the Wolcott Mining Company ground, located about 200 feet west of the Carbonate fault. At a depth of 200 feet the well recognized iron and manganese was found dipping eastward, and carrying some carbonates in pockets. Next adjoining on the west, Mr. Campion took up some land and on the Elk claim, also struck "contact" and got good ore at a depth of 250 feet. This shaft was still 400 feet west of the Hussey. Then Major Bohn himself continued the western extension for 500 feet beyond the Elk fault and sunk a shaft whose results greatly discouraged them as they thought this fault must certainly mark the extreme western limit of the ore-bearing strata. Major Bohn then dropped down to the Penrose, still west of the Elk fault and shaft, some 1,200 feet. First he shafted down through 318 feet of moraine matter, and then he put down a diamond drill for 145 feet and struck the overlying white porphyry, then 36 feet of shale, 9 feet of contact matter and 70 feet of "blue lime," total 260 feet at this point, satisfied at having struck the right formation, drilling was discontinued, the shaft was sunk 500 feet, 300 feet being added. There was a total in the shaft of 500 feet from

the surface to the top of the lime. Then he began drifting. The presence of the porphyry and lime fully satisfied him that he was on the right zone, and he then went to regular mining, encountering at first large volumes of water.

Then Messrs. Smith and Moffat took hold, next Mr. Bohn started on the Lazy Bill, now part of the "Star" mine. This drill-hole went down 570 feet. The location of the drill is 400 feet from the Penrose. Nine feet of ore was cut by the drill in one body, but this has not yet been reached by the shaft. From this experiment Mr. Bohn went on to the Bon Air which is 1,630 feet west from the Penrose, thus ever extending the area of experiment westward. The same geological features were met and at 500 feet from the surface 8 feet of good ore was encountered.

The first work was in 1891. The present Bohn shaft and Valentine shaft are alongside one another. The Bohn follows the Bon Air to the west. The panic of 1893 stopped the whole business. The Penrose and Bon Air were then both shipping and proving satisfactorily Mr. Bohn's theory. In 1894, after recovering from the panic, Major Bohn procured the ground named after him and sunk the Bohn shaft without previous experimental drilling. The following was the character of the ground pierced: 252 feet wash or glacial and lake-bed matter; 74 feet white porphyry; 20 feet Black porphyry; 45 feet Birdseye porphyry; 75 feet "blue limestone."

In this dolomitic Leadville limestone the ore was found, and the Bohn mine soon became a heavy shipper.

The miners' strike of June 16, 1896, stopped everything and killed Leadville for nearly three years. The mines very soon became full of water owing to stoppage of the pumps and remained so till a pumping association was organized in 1896, which put up \$50,000 for unwatering the mines. This was inaugurated whilst the strike was still in progress, Messrs. Smith & Moffat putting up one-quarter of the sum. The strike was declared off in September. Then there was a dragging along and a delay of a year, nobody being willing to put up the money. Major Bohn then organized a "Home Mining Company" which was well endorsed by the leading Leadville papers, and the pumping association started the first of October, 1898, and unwatered the mines. This company included the "Home Mining Company" and several other companies' properties.

After the pumping association declared the mines unwatered on the first of August, 1899, each party took possession of its own mine. It was then the Home Mining Company got possession of its properties, viz.: the Penrose, Star, and Bon Air, and capital was put into the development work. The mine for eight months carried its own expenses, including opening and re-timbering and new development. All this was paid for out of the product of the mine. The mine has paid 150 per cent. dividend up to June 1st, 1900. It has at least 50,000 worth of property, including pumps and machinery. Lately Mr. Bohn's son, believing in the theory of his father, went still farther West and put down the Valentine shaft 2,500 feet from the "Bon air" to the southwest. So far he has gone down through 312 feet wash; 118 feet porphyry; 3 feet contact matter; 54 feet limestone; total 487; thus proving the westward continuity of the formation. Mr. Bohn estimates the area as three miles wide towards the west from the Carbonate fault, extending from the City of Leadville 12 miles to the north and 8 miles to the south, an area approximately 15 X 15 miles or a total of 608 square miles.

VISIT TO SOME OF THE "DOWN TOWN" MINES.

The first mine we visited was the Penrose, one of the prominent "down town" mines, just on the western edge of the city. It is equipped with a 100 H. P. hoister with drums 72 in. X 36 in., cylinders 14 in. X 16 in., round rope one inch diameter 1,000 feet on each drum, and provided with a Lane clutch. The present depth of the mine is 540 feet. Water was met at 200 feet, giving 400 gallons per minute. This is controlled by a Knowles compound duplex condensing pumping engine. Snow pumps are used as sinkers. There are two of these with capacity of 1,500 gallons per minute. The Coronado moves 300 gallons and at different places 3,000 gallons per minute are raised. Snow pumps are rated as throwing 750 gallons each from 500 feet depth. The Snow pump has two cylinders, duplex tandem, giving speed power at any depth. The water runs down the street to the Arkansas. There are nine boilers, two 100 H. P., six 80 H. P., and one 60 H. P.

Besides the hoister mentioned there is a Webster, Camp & Lane No. 2 reel with flat band 4" wide rope; the diameter of the reel is 7 feet. We found here, as in many of the other mines throughout the West, that the flat band or flat rope system is being abandoned and they are returning to the old-fashioned round rope. One cause of this seemingly retrograde evolution is due to the great weight of the rope in hoisting.

On descending into the mine we were struck by the terrific amount of crushing of the stulls and pillars by swelling of the

overlying white porphyry. This crushing occurs in almost all the Leadville mines, and is only surpassed in the deep mines of Butte, Montana, and some at Aspen, Colorado. Pillars 18 in. diameter of squared timber were crushed into kindling wood, and lagging was often bulging outward and snapped. When a man begins to think of opening up a mine and counts up the cost of timbering, it is well for him to consider this item of crushing and consequent repairs and re-timbering.

The ore occurs as masses of black manganese and iron lying immediately under the overlying white porphyry, replacing the dolomitic limestone that lay below it. This body of manganese and iron carries more or less silver. Occasionally rich patches of lead carbonates occur and now and then unoxidized patches of galena.

A notable feature in the mine is the white dolomitic sand in the drifts; another striking and interesting feature are the holes or water channels descending into the drifts, some of them large enough for a man to crawl into. It was through these channels, now dry, that the mines were flooded and so long remained full of water; they seem to come in from a northerly direction and are quite common in the various drifts. They too doubtless aided largely in bringing in the white dolomitic sand which came in in such volumes that after the mines were unwatered the drifts were found packed hard and solid with them and had to be opened anew, often a very difficult undertaking owing to the flowing in of watery material, like a quicksand. In some places piles had to be driven in to head off the work and excavations made underneath them.

After the Penrose we visited the Star mine, here they have a Fairbanks, Morse & Co. friction hoist with a cylinder 12" x 16", and with a 1 inch rope. The developments of this mine are very similar to the Penrose. Thence we walked westward to the Bon Air mine, celebrated as the scene of a notable accident in which a large portion of the surface of the mine collapsed and shut in the shafting, imprisoning for several days a number of men, but fortunately not killing them or entirely shutting off their air supply. Signals and communications were made with the surface and food lowered them, and they were kept alive for several weeks until a rescue shaft could be run down from the surface to reach them.* This shaft is visible on the dump outside the plant. The collapse was caused by seepage of surface waters. To temporarily avert further outflow of material, great quantities of hay and straw were thrown in and found successful.

A long, high trestle bridge runs out from the mine, dumping the ores by a series of wooden aprons on either side the track to the cars below. The isolated aprons at intervals are not considered so good as one continuous sloping apron on either side along the trestle. From the top of this trestle bridge above the mine we have a fine view of the region west and of the Arkansas Valley, bounded on the west by the magnificent snow-capped Sawatch Range with the Arkansas River flowing parallel with it not far from its base. It is this area that is now the center of interest as to its possibilities of being underlaid with ore-bearing strata. We can see steps advancing towards the solution of this great problem by the outlying shaft of Mr. Bohn's son, and by the Maple Street shaft. These are on the fore front of the bold prospecting line, although we saw the commencement of a shaft by Mr. Bohn some way below Malta which had not as yet reached any solid foundation.

Another well-timbered shaft was being put down on Capitol Hill near the north end of the principal street of the town, and at the time of my visit there was hourly expectation of striking the solid formation; so far they had only penetrated through drift and lake-beds.

Besides these frontier or prospecting line "down town" mines, we visited some of those farther up in the city, such as the Midas and M. A. B.; these are right in the heart of the town and by the side of the principal streets, their dumps carefully timbered up beside the roads. These mines with depth have been found to contain large bodies of manganiferous iron, carrying silver and some lead, as well as a great amount of water. They seem to be located in a shallow synclinal basin, as the strata are found dipping towards a common center, and over 500 feet of drift and lake-bed fills the upper portion. The ore occurs below the porphyry, replacing by substitution the underlying limestone. All these "down town" mines are connected by workings; their main trouble is water, which is controlled by large Knowles pumps, pumping 1,000 gals. per minute into tanks and up to the surface. A Snow pump is also used for the lower workings and at the A. M. W. mine the shaft is 970 feet deep. They are using a reel and flat band hoist at present. The water is pumped up by triple expansion pumping engines with high pressure cylinders 20 inches in diam.; intermediate 34, low pressure 44, 36 inch

stroke, 10½ in. plungers, built for steam pressure of 150 pounds. There are 7 boilers, each of 100 horsepower and carrying 150 pounds of steam.

The Midas and M. A. B. are severally 550 and 1,000 feet deep, pumping 150 gallons per minute. They pay their pro rata of pumping to what is called the Pump Association. Individual mines generally do their own pumping. It would be a great boon if these up and down town mines could be unwatered by a long drainage tunnel, starting in from the Arkansas Valley, but the conformation of the ground will not admit. The greatest depth that could be attained by such a tunnel would not exceed 500 feet, and many of the mines are far below that.

Another item that will have to be considered in future developments of "down town" mines will be dumpage room right in the populous part of the city.

THE YAK TUNNEL.

As an example of a drainage and exportation enterprise we visited the celebrated Yak Tunnel, which is down under Iron Hill, and whose ultimate goal is the distant gold-belt of Breece Hill and the Little Johnny and Ibex Company's mines. For the first nine hundred feet you pass under a covered shed-way before entering the solid rock. This rock consists of red granite, quartzite, porphyry and Paleozoic limestones. Much of this is timbered with heavy timber and in some places with lagging. Most of the well-known Leadville formations are cut at a slight dip and several faults are passed. Ores are found at the usual contacts. A good deal of the latter part of the tunnel is in red granite. We pass on our way two or three side tunnels and workings which have come down from the Silver Chord, and other mines. There being but little dip to the strata comparatively few different formations or ore deposits are encountered by the tunnel, and at present far less water drains out than might have been anticipated. On one of the side tunnels they are sinking and taking out ore with small handy little hoisting engines, driven by compressed air only, which are often used inside some of the Leadville mines. The success of the Yak Tunnel will largely depend upon when it reaches and underdrains as well as exports from the Gold-belt region, which it will tap at considerable depth. At present a length of 8,500 feet has been attained.

A VISIT TO THE "RESURRECTION" MINE.

A visitor who remembers Leadville in its earlier days, when silver was at its height will be struck as he rides towards the Mosquito Range with the vast amount of huge dumps and big works that at present are for the most part idle. These mark the sites of many of the well-known and once celebrated old silver stand-bys that made Leadville in early days celebrated. Such monuments would have at first a depressing effect were it not for the great amount of young and very valuable mines that have sprung up, in some cases as it were from the roots of the older ones and in others in new and more extended portions of the Leadville field from which little was once anticipated. We have in this connection the "down town" mines on the one side and the Gold-belt mines on Breece and Little Johnny Hills on the other, but these are not all, for from the latter again a systematic prospecting has extended the gold-belt and ore-bearing area over many unlooked for parts. A prominent example is that of the "Resurrection" group. This lies on one of the faulted step-like blocks of the westerly flank of the Mosquito Range, on the edge of an amphitheater in whose lap lie glacial lakes supplying Leadville with drinking water. As we pass along the hill sides, we look up on Breece Hill on the right and see the great yellow dumps of the Little Johnny, like so many piles of yellow sawdust from a monster saw mill. The Ibex, Little Johnny and Breece Hill mark the line of the so-called Gold-belt, while on a humbler hill, called Little Ellen below is the Resurrection, its works crowning the hill, surrounded at various levels by a number of mines on the same belt. As the strata dip from the Resurrection down to the amphitheater several of these mines are on the flat below.

The succession of strata through which the main shaft goes are first a few hundred feet of Weber grits and shales, then white porphyry, then blue limestone. The ore occurs in the limestone as well as at the line of contact with the porphyry. It consists of iron oxide and lead carbonates, carrying a certain amount of gold with the lead and silver, below this is the parting quartzite, about 25 feet thick, and below this is Silurian limestone in which some gold is found. The shaft is down about 1,000 feet. There is a good deal of water in the lower portion which is controlled by powerful pumps. The mine is heavily timbered, and the drifts meander through it. There is the same great strain on timbers shown here as elsewhere in Leadville. The ore is a good smelting ore on account of the carbonates of lead which it carries, but there is a great deal of siliceous matter with it.

* See Mines and Minerals, Vol. XIX, p. 459.

THE MESABI RANGE.

A Description of the Ore and Also of the Open Pit, the Caving and the Milling Methods of Mining It.

By Cyril Brackenbury, M. E.*

The Mesabi range in the state of Minnesota is a low range of hills running a little north of east and south of west and lying about 60 miles northwest of Duluth. It is separated from the Vermilion iron range on the north by a granite ridge, which is called the Giant's range.

The ore bodies lie on the southern slopes of the low hills which form the Mesabi range. Near the Giant's range, the dip is steep, but it flattens out almost to a horizontal away from the granite. These deposits occur in lenses, which sometimes form

basins, and vary from a few feet to three or four hundred in depth. At the Oliver mine a drill hole has shown 335 feet of ore. The ore bodies generally lie in a south-easterly direction, and often attain several thousand feet in length, though usually only a few hundred in width. The dip is slight and generally inclines to the south.

The ore-bearing rock is a jaspery chert called "taconite," which is found, broadly speaking, under the black slates called "animikie," and

(a)

(b)

(c)

PLAN AND SECTION SHOWING CAVING METHOD.

over the Pewabic quartzite. The whole region is covered with glacial drift, which varies from a few feet, to over one hundred feet in depth, and the ore bodies are found under this, an outcropping rock being a very rare occurrence.

The ore is dark red, brown, or blue, and of a soft, earthy texture with some hard streaks running through it. It consists chiefly of hematite and the blue ores are generally the richest in iron and most free from phosphorus. The ore "in place" averages about twelve cubic feet per ton, or about 18 cubic feet of loose ore per ton.

The ore deposits are thought to have originated by the replacement process, the taconite having been dissolved out by water containing carbonic acid, some of which may have been taken up from the rock itself which contains calcareous streaks.

carbon dioxide passes on into the rock and aided by pressure readily dissolves iron. The water becoming saturated with iron, then passes into a zone of oxidation, such as a fissure, the excess of oxygen and the release of pressure cause the ferrous salts to be oxidized and deposited while the silica is attacked and removed by the alkaline solution.

The two principal companies owning mines on the Mesabi Range are the Minnesota Iron Co. and the Lake Superior Consolidated Iron Co. Each of these companies controls a railroad, and has its own steamers, which transport the ore to the lower lake ports. The Minnesota Iron Co. controls the Duluth & Iron Range railroad, which carries its ore to its docks at Two Harbors on Lake Superior, in which place are situated the company's railroad shops and chemical laboratories. The Lake Superior Consolidated Co. controls the Duluth, Mesabi & Northern railroad, which carries its ore to the docks in Duluth.

The proportion of iron ore taken from the Mesabi range, as compared with that obtained from the Marquette, Menominee, Vermilion and the Gogebic ranges, has increased annually very rapidly since the year 1892, when the Mesabi range commenced shipping with 4,245 tons from the Mountain Iron mine.

The following table will show the relative increase of ore shipped from the Mesabi, as compared with that shipped from the other ranges for the years 1892 to 1899 inclusive, and also the total ore production from each range from the first year of its shipment:

From this table it will also be noticeable that the shipment from the Mesabi range in the year 1899 was nearly twice that of the Marquette range, more than twice that of the Menominee, and also of the Gogebic, and more than three and a half times that of the Vermilion range.

In the year 1899, the Mountain Iron mine and the Fayal mine each shipped over one million tons of ore. On the Mesabi range the Minnesota Iron Co. is only shipping from four of its mines this season, namely, the Fayal, Genoa, Elba and Auburn.

The mines on the Mesabi may be divided into three general classes, namely: (a) open pit (b) underground and (c) mines which are a combination of the two preceding classes having part of their workings underground and part open pit.

The general method of open pit mining consists in first stripping off the surface glacial drift by means of steam shovels and loading it into cars and then attacking and transporting the ore itself in the same manner, having first loosened it up by blasting. As soon as a sufficiently large area of the surface deposit has been removed, then the first cut is made in the iron ore itself, the

DRIFT READY TO CAVE.

GROSS TONS OF ORE SHIPPED.

Name of Range.	1892.	1893.	1894.	1895.	1896.	1897.	1898.	1899.	Total Production.
Mesabi	4,245	613,620	1,793,052	2,781,587	2,882,079	4,275,809	4,613,766	6,926,384	23,590,543
Marquette	2,666,856	1,835,893	2,059,330	2,097,838	2,604,221	2,715,035	3,125,039	3,757,010	56,135,271
Menominee	2,261,499	1,466,197	1,137,919	1,923,798	1,560,467	1,937,013	2,522,265	3,301,052	30,754,758
Vermilion	1,167,650	820,621	948,513	1,077,838	1,088,090	1,278,481	1,265,142	1,771,502	18,535,360
Gogebic	2,971,991	1,329,385	1,809,468	2,547,976	1,799,971	2,258,236	2,498,461	2,795,856	28,341,340

The process is thought to have taken place somewhat as follows: Atmospheric waters containing carbonic acid and some alkaline salts penetrate the rock and oxygen is taken up by unoxidized elements in the rock, causing carbon dioxide to be set free. The water thus free from oxygen, but highly charged with

stripping being continued and the area of ore exposed being constantly enlarged. After the first cut in the ore has removed a large enough area, the second cut is made, the first cut and stripping being still continued outwards. This process is continued, a new cut being made whenever a sufficiently large area has been uncovered by the last cut. The height of the stripping bank varies according to the depth of the surface deposit, and where

*Reprinted from the Daily Mining Gazette, Houghton, Mich.

the surface deposit is deep it necessitates more than one cut being made to remove it and to uncover the ore. As a general rule 25 or 30 feet can be conveniently removed by the steam shovel in one cut.

The Mountain Iron mine on the Mesabi range is a good example of a purely open pit mine. Here the topography of the deposit is well adapted to this method of mining. The water is removed by natural drainage through a ditch about 12 feet deep, made at the side of the track in the Rathbun cut. The outlet for the loaded cars has grades opposing the loads, as is of course generally necessary in this method of mining. Two locomotives are used for each steam shovel, one to handle the empty, and one the loaded cars. The only delay, therefore, that necessarily occurs is when the shovel is moved forward. Some great records in steam shovel work have been made here. The best record with the largest shovel is said to be 171 26-ton cars, or 4,446 tons in 10 hours. A shovel crew consists of five pit men, an engineer, a cranesman, and a fireman. The ore is first loosened by blasting before being attacked by the shovel. The ore is classified into different grades according to the percentage of iron and phosphorus. In order to do this the banks are carefully sampled from 25 to 50 feet ahead of the shovel, depending upon the kind of ground, and the results are used to guide in loading the cars. Samples are also taken of every trainload, and of cargoes if necessary.

There are several methods in use for working underground mines; often more than one method being used in the same mine. The Genoa iron mine belonging to the Minnesota Iron company is at the present time a good example of a purely underground mine. Many mines on the Mesabi range have originally started as purely underground workings, but have later done stripping and become mines of the third class in which both underground and open-pit mining are carried on at the same time. The Fayal mine, one of the best properties of the Minnesota Iron company, is now on this list, having been worked, however, until 1898 as a purely underground proposition.

At the Genoa mine the method of mining now employed is what is known as "sub-drifting and caving" method. This method may be briefly described as follows: First the hoisting shaft is sunk to the bottom or main level at an angle of 66 degrees, and in some cases a vertical timber shaft is also sunk to the bottom. Then the main level is blocked out by drifts. Upraises are made through the ore body, and chutes placed at the bottom.

OPEN CUT MINE WORKED BY MILLING SYSTEM.

The sub-levels are then started, only every alternate sub being connected with the timber shaft, and generally only the main level with the hoisting shaft. The sub-levels are about 12 feet apart vertically. The top sub is first blocked out with drifts, and then the blocks or pillars of ore removed by slicing back towards the shaft and the surface is allowed to cave in, the floor being first covered with rough inch boards as each drift and slice is made. By slicing is meant a series of short drifts run through the pillar to remove the ore from it, each slice being timbered in the same way as the drifts which were made in blocking out the level.

The ore from the slices is taken to be dumped in the chutes, either by means of wheelbarrows or tram cars, according to whether the place being worked is near to, or far from the chutes. In the Genoa mine the raises for the chutes are placed 50 feet apart, and in the Fayal they are 100 feet, consequently in the Genoa wheelbarrows are chiefly used in the sub-levels for carrying the ore to the chutes, while in the Fayal cars are used.

When the first "sub" is sufficiently caved, the second sub is

STEAM SHOVEL AT WORK.

then blocked out and caved, this process being carried on down to the bottom or main level, from which the ore is taken out last of all. By this method a great deal of timber is used, but it is simply drift timber consisting of two legs and a cap, lagging being put in overhead and planking on the floor below. The timbering is not nearly so difficult or expensive as in the square-set method, since all the timber can be easily taken down the timber shaft or timber chutes, and from thence transferred along the drifts and put in place. It does not have to be pulled up through raises or hoisted into place, as is necessary in the square-set-room method; also the posts used do not have to be nearly so large. This method of sub-drifting and caving appears to be well suited to working these soft ore deposits in which patches of low-grade ore and rock occur. The chief advantage of this method compared to square-setting is that there is much less waste in the pillars from crushing and practically all the ore may be safely taken out, and at the same time low-grade ore and rock can be left with very little inconvenience. It is a safe and rapid manner of getting the ore but has the disadvantage of requiring an immense amount of timber.

In the Genoa mine a vertical shaft especially designed is used for handling the timber. The timber is cut on the surface at the timber-pile, loaded on trucks and wheeled onto the timber-cage at the top of the shaft. The weight of the timber in the trucks is sufficient when the brake is released to raise the balance weight from the bottom and cause the cage to descend. On reaching the level the timber trucks are pushed off the cage and along the tracks in the drifts to the nearest place to where the timber is required. Then the empty trucks are pushed back to the shaft and onto the cage and hoisted to the surface by means of the counter balance which is sufficient to raise the cage with the empty trucks. Injured men, empty cars, etc., may also be brought up in this cage more conveniently than in the main hoisting shaft.

At the Fayal mine timber slides are used for lowering the timber into the mine. They are made by putting raises to the surface on an incline of about 38 degrees. These raises are 5 ft. $\times$ 5 ft. in section and are fitted with slide-ways down which the timber slides. The slide-ways are flattened at the bottom to diminish the velocity of the sliding timber. The drifts in the main level and also some of the drifts in the sub levels have 12-foot caps and 8-foot legs making 10 ft. $\times$ 8 ft. in the clear. The slicing drifts have caps only 8 feet wide and generally legs of the same height.

The square-set method of mining was at one time quite extensively used in working these mines, but now has been largely replaced by the above described method of sub-drifting and

caving. But as it is still used to some extent perhaps a short description of this method may be desirable. In the Fayal mine a special system is used for removing the pillars between the rooms. The rooms are worked out by overhead stoping, and square set timbering put in three sets high, and three sets wide, leaving a pillar between the rooms of the same width and height. In order to remove the ore in these pillars a plan was introduced by the head mining captain which I believe has never been used

STEAM SHOVEL METHOD OF MINING.

elsewhere but has been found to work very successfully there. At the farthest end of the two rooms and next to the rock, the lower portion of the pillar between the rooms is first removed and the bottom set put in place, next the portion above is removed and the second and then the third set erected over the first set. This process is carried on from the back forwards a distance of three or four sets and when the weight on the timber between the pillar and the rock becomes so great as to threaten crushing it, then this timber is blasted down and the sand allowed to cave in, thus taking the strain off from the remaining part of the pillar, and allowing of its removal by the same process continued. In case the weight on the timber in the rooms should cause them to cave before the pillar was removed then the pillar would be taken out by top slicing as in the subdrifting and caving method. The ordinary method of mining by square set rooms is different to the special method used in the Fayal as described above. At some of the mines the rooms are caved by blasting in the roof and timbering while in others they are filled by running in the overlying drift through raises put up for this purpose, and it is only after the rooms have been caved or filled, that the pillars between are attacked and removed. Filling the rooms is a slow and expensive process, and if the rooms are caved, the pillars become broken and crushed and there is much loss of ore, as only a portion of the pillars can be removed with safety, the rest having to be left and wasted. Altogether it appears that this method is not a satisfactory one to use in these deposits, and it seems likely that it will soon be almost entirely abandoned.

A feature common to the Fayal, Genoa, and Auburn mines, is the use of special rooms underground for thawing dynamite. These rooms are warmed by steam heat, and contain lockers for the powder, one of which is assigned to each contract party. No candles are allowed in these rooms but a reflector is placed on the door outside on which the men place their candles thus obtaining sufficient light in the room without the danger of fire.

Many of the mines which were originally started either as simple open-pit, or purely underground are now worked by both these methods. This combination method of mining is locally termed the "milling" system. In the Auburn mine two levels have already been opened, the first having about 65 feet of ore above it, and the second level about 60 feet. The first level was laid out on the diagonal plan, the branch drifts having the main center drift at an angle of 45 degrees. The second level has been laid out on the ordinary rectangular plan, the branch drifts running at right angles to the main drift from the shaft. From each level the method of mining is the same, the ore above the first level being removed before the second level was used. From all the drifts raises were made to the top of the ore, which had previously been uncovered by stripping with steam shovels, which shovels after removing the surface deposit, are also employed in parts of the mine to load the ore directly into ore cars as in the simple open pit method. When the raises reach the top the ore is "milled" (is broken around and sent down) through them to the chutes below on the main level, from whence it is loaded into cars, trammed to the shaft and hoisted to the surface. The first raises are placed 40 feet apart, and when these are mined out a second series of raises are put up half way

between the first to tap the pyramid of ore left between the first. By making the raises a little larger at the bottom than at the top, it tends to prevent the ore sticking or becoming jammed in them. Holes are drilled around the sides of the craters by driving down with sledges pointed 1½-inch steel rods, varying in length from 5 to 13 feet. The time required to drive these rods varies with the hardness of the ground and the depth of the hole, and may be from ten minutes to an hour. Two to four strikers may be employed. To draw these rods which often stick very tight, clamps are fastened to the top, and railroad jacks are placed under the projecting arms of the clamp. When a rod has been drawn the first six or eight inches, it can generally be drawn the rest of the way without much trouble. These holes are first "chambered" with three or four sticks of 50 per cent. dynamite and then charged with three to ten 25 pound kegs of black powder. To prevent men from being carried into the raises by the sliding of the ore on the sides of the crater, ropes are kept within their reach. Through neglect of this precaution by the men, accidents of this nature have happened, but the men have been rescued from the craters by placing around them barrels, pieces of smoke-stack or any tube large enough to keep the ore from falling in upon and smothering them. With this protection the men have time to work themselves loose, and can be pulled out.

The Fayal, which shipped over a million tons in 1899, is the most interesting mine on the range. Here the "top-slicing and caving" method, and more than one form of the "square-set-room" method of underground mining are in use. Also "open-pit" work is done with the steam shovel and the "milling" combination method is used. In conclusion it may be said that although large shipments are being made annually from this range, yet there are vast areas of land which are known to contain good ore, which have not yet been touched, and it seems most probable that the Mesabi range will continue for years to come, to be the leading iron ore producer of the Lake Superior region.

Freight Rates From Buffalo to Upper Lake Ports in 1899.

Box Car Loading.

Several months ago we published a description of a box car loader which was manufactured at Ottumwa, Ia., by the Ottumwa Box Car Loader Co. for the purpose of loading coal into box cars. At that time the industry was in an embryo state, and while the machine had been demonstrated to be more or less of a success, it had not come into use enough to entitle the manufacturers to say that they had fully demonstrated that it was what the coal operators of the country wanted. They now, however, report that they have sold and placed nearly fifty of these loaders in different parts of the United States and Canada, and their orders are constantly increasing.

The question of loading coal into box cars in proper condition for the market, and without delaying and decreasing the capacity of the mine, has been a serious problem with coal operators for years. Some companies have arranged a special track on which to load box cars, and have dumped only a portion of the output of the mine into box cars, thus giving the men ample time to keep the coal away, and thus avoid delaying the mine as would be done were all the coal dumped into the box cars. This however, has if anything added to the expense of loading for the reason that the men are not so crowded at their work, and consequently do not take care of as much coal as they would otherwise. At many of the mines the estimated expense is 4 cents per ton for handling coal after it has been dumped into box cars. The manufacturers of this Ottumwa loader claim to be able to do the loading for from ½ cent to 1 cent per ton. Such a saving as this is an important item, and especially if it is combined with the advantage of having the coal loaded in much better condition for the market because of more careful handling. There are always seasons of the year when it is difficult to obtain enough open cars, and if parties are prepared to do box car loading, it will often avoid having to shut down their mines.

LAKE SUPERIOR COPPER MINING.

Facts in Regard to the Enormous Production of the Region and the Large Returns in Dividends.

Written for MINES AND MINERALS, by Horace J. Stevens.

The year 1899 was marked by the largest dividends ever paid by Lake Superior copper mining corporations. The earnings for the present year will probably be nearly or quite as large as last year, but the dividend record will be smaller, for two reasons, one of which is the reduced dividend paid in June by the Calumet & Hecla, owing to the fire of the preceding month in that mine, the extent and damage of which was then undetermined. The second reason is that the dividends of the year 1899 were abnormally large, owing to the conflict between the calendar year and the fiscal year of the Calumet & Hecla. That mine has never paid more than \$8,000,000 in any of its fiscal years, which end on April 30, but for the calendar year 1899, the total dividend disbursements were \$10,000,000. This swelled the grand total of Lake Superior copper dividends for 1899 to the magnificent sum of \$12,318,000, or nearly double the amount paid in any preceding year. The wonderful growth of the Lake Superior copper properties in earning power is shown by the following table giving dividend payments for the past ten years:

Year.	Dividends.
1890	\$3,415,000
1891	3,540,000
1892	3,260,000
1893	3,520,000
1894	2,380,000
1895	3,280,000
1896	3,985,000
1897	5,431,000
1898	6,853,000
1899	12,318,000
Total	\$47,982,000

For the current year, dividends paid and declared to and including Oct. 1 are as follows:

Mine.	Dividends.
Atlantic	\$80,000
Calumet & Hecla	5,000,000
Osceola	279,000
Quincy	900,000
Tamarack	420,000
Wolverine	240,000
Total	\$6,919,000

In addition to the dividends listed in the foregoing table, the following amounts are likely to be disbursed as profits to shareholders by the mines named, before Dec. 31:

Mine.	Dividends.
Calumet & Hecla	\$2,000,000
Osceola	279,000
Tamarack	420,000
Total	\$2,699,000

This makes a probable total of \$9,618,000 in dividends for this year. There is a possibility that an even larger dividend may be declared by the Tamarack, and the Calumet & Hecla may add the million withheld in June, in which case the dividend disbursements of the year would considerably exceed ten millions.

With the payment of its last dividend, in August, the Quincy mine brought the grand total of dividends from Lake Superior copper mines above the hundred million dollar mark. The following table shows the dividend payments by decades, the first item covering the year 1849 only, when the Cliff mine paid the first profits earned by any Lake Superior copper mine, and the last item covering dividends paid or declared to and including Oct. 1, 1900:

Period.	Dividends.
Year 1849	60,000
Decade ending 1859	2,340,000
Decade ending 1869	3,770,000
Decade ending 1879	18,298,820
Decade ending 1889	23,762,500
Decade ending 1899	47,982,000
9 mos. to Oct. 1, 1900	6,919,000
Total	\$103,832,120

The mining districts of the world that have paid a total of more than one hundred million dollars in profits are very few in number. The grand total of one hundred millions achieved by Lake Superior copper mines places this district in advance of all other American mining fields in actual profits earned and paid.

The dividend payments of the districts, to and including Oct. 1, 1900, have been made by the following named mines:

Mine.	Total Dividends.
Atlantic	\$860,000
Cliff	2,518,620
Central	1,970,000
Copper Falls	100,000
Calumet & Hecla	70,850,000
Franklin	1,240,000
Kearsarge	160,000
Minnesota	1,820,000
National	\$20,000
Osceola	8,373,500
Pewabic	1,000,000
Phoenix	20,000
Quincy	12,320,000
Ridge	100,000
Tamarack	6,690,000
Wolverine	510,000
Total	\$103,832,120

An interesting feature of the past mining operations in this field is the ratio of dividends to the gross value of the copper production. Preceding the year 1849, when the first dividend was paid, but a few hundred tons of copper had been secured from Lake Superior mines, within modern times, though from the evidence of mining left by prehistoric races it is certain that many hundreds and perhaps many thousands of tons were secured in ages long past by the aboriginal residents of the North American continent. The total value of the Lake Superior copper product, by years, for the past ten years, is appended:

Year.	Value Product.
1890	\$15,819,960
1891	14,574,727
1892	12,431,624
1893	12,105,145
1894	10,852,122
1895	13,877,109
1896	15,758,935
1897	16,530,843
1898	17,829,871
1899	26,088,382
Total	\$155,878,718

During this same period the dividends amounted to \$47,982,000, or nearly one-third of the gross value of the copper. The estimated value of the copper product of Michigan for all years, from 1845, when the first product of twelve tons was secured, until the close of 1899 is \$389,584,204. The dividends in the same period were \$96,913,120, showing that of the gross value of the product for 55 years, 24.8%, or almost exactly one quarter, was returned to shareholders in dividends.

There is, however, a dark side to this roseate financial showing. Tens of millions have been sunk in various mining enterprises, for which little or no return has been secured. It is probable that more than half of the money so lost has been wasted, through incompetence or otherwise, leaving less than half of the money actually sunk without returns for investment in properties which apparently had reasonable chances of success under good management. Mines like the Calumet & Hecla are not lying around loose, for the benefit of those who seek, and even a good property requires millions for its development.

In addition to being one of the most profitable mining fields of the world, it may be stated without fear of contradiction that the Lake copper district is also one of the most expensive in which to open a mine. No property should start existence with less than a quarter of a million cash in the treasury, after acquiring title to the lands and paying all preliminary expenses. Half a million in the treasury is much to be preferred to a quarter of a million and an even ten hundred thousand dollars is still better. The Isle Royale Consolidated, now engaged in reopening a group of old mines in this city, begun corporate life less than four years ago with a cash surplus of one million dollars in the treasury, after acquiring title to the three mines in the consolidation, and in 1899 the Miners Copper company was absorbed, with its cash surplus of one million, giving the Isle Royale Consolidated the magnificent sum of \$2,000,000 for the development of its property.

It is probable that Calumet is now the largest mining camp in the United States. This honor has long been claimed by Butte, Montana, but the recent Federal census gives that town a population of only 31,000, instead of the 50,000 to 60,000 claimed for several years. Calumet, unfortunately, is not a city, but a collection of locations having village and township governments. It sprawls over three townships and is located in two counties. As there are upwards of 9,000 men employed in and about its mines, to say nothing of about 2,500 men engaged in various other occupations, there can scarcely be less than 40,000 people there. The number of mine employes is materially larger than in Butte, where about 7,000 men are employed in and around the mines.

It is probable that by the close of this year between \$5,000,000 and \$6,000,000 will have been invested in new stamp mills and

machinery within three years by the Lake Superior copper mines. The size and quantity of machinery coming into the district is marvelous and can be understood only from actual sight. It is only within the past few years that the Calumet & Hecla has been able to get its largest steel castings made in the United States, previous orders having been filled by Friederich Krupp, from his works at Essen and Magdeburg, Germany, he being the only manufacturer in the world then capable of turning out steel castings and forgings weighing fifty to seventy tons. American manufacturers are now equipped to care for this work, though not every town possesses establishments that can turn out such jobs.

The Calumet & Hecla is now using about 350 power drills in its mines. No other mine in the world has so many as 250 power drills at work.

Among the improvements in the district none are more noticeable than the many new stamp mills. No mill is being built of less capacity than 500 tons daily, and but one of that size. The mills not only cover vast areas themselves, but require an average frontage of one mile each, upon Lake Superior or some of its arms, to care for the enormous volume of sand carried out daily. The Osceola and Tamarack have each completed new mills within the past fifteen months, and the new mills of the Arcadian and Franklin were put in commission only last summer. The Calumet & Hecla is building a big new mill to have six steam stamps, which will care for the rock from the amygdaloid openings of the mine. The Quincy is building a large new mill, the operation of which will soon be reflected in increased production and enlarged profits. The Mohawk will build a mill next season, at the mouth of the Tobacco river, on Grand Traverse Bay, Lake Superior. The Centennial will probably build a new mill also next season, its present milling plant being too antiquated for economical production on a large scale. The steel superstructure of a new four-stamp mill for the Baltic will be begun within ten days, opposite the mill of the Atlantic, at the mouth of the Salmon Trout river, where the first steel gravity dam in the United States is now nearing completion. The Trimountain and Champion mines are both casting about for suitable millsites, the latter having a tract under option at the mouth of the Misery river. The Isle Royale is completing a mammoth new mill at the mouth of the Pilgrim river, Portage Lake. The Mass is building a one stamp mill at Ogima, on Keweenaw Bay. The Adventure will probably begin a mill next year and the management of the Michigan is seeking a suitable site, the mill test of 1,000 tons recently made at the Atlantic mill having proven satisfactory. The cost of the buildings and machinery of the least of the mills enumerated in the foregoing list will not fall below \$100,000 and the average will be nearly double that amount. Fifteen mills, built within the past two years, now building or planned for next year, have been enumerated in the foregoing list, and it is probable that their collective cost will range between two and a half and three millions of dollars.

In addition to the cost of building and equipping these mills, between two and three millions have been expended on new railroads, built to serve these mines. The Mineral Range railroad built a branch line to accommodate the Franklin, Franklin Junior and Arcadian mines. The Mohawk is building seven miles of new line to connect with a seven-mile logging road running to its millsite. The Arnold built a railroad in Keweenaw county to connect its mine and mill. The Osceola and Tamarack mines have completed a survey for a projected line to connect their mines at Calumet with their mills on Torch Lake. The Mineral Range is completing a forty mile extension, built to connect the mine and mill of the Mass company, and the Copper Range Railroad company has built and equipped a forty mile railroad line running from Houghton to Mass City, Ontonagon county, at a cost of perhaps a million and a quarter, and will build a fifteen mile extension to Calumet next year.

In the way of new machinery plants, costing from \$10,000 to \$1,000,000 each, at least a full column would be required for a mere enumeration. Every Lake Superior copper mine which is not moribund has been investing in machinery, and the machinery so bought has usually been of the most massive and costly nature. The hoisting plants range from a few hundred horsepower to 8,000 horsepower each. The fifty thousand horsepower now being generated at Niagara Falls would all be required to run the Calumet & Hecla mine. At a single one of its seventeen great shafts there is an 8,000 horsepower hoist, steam for which is supplied by 10 boilers of 1,000 horsepower each.

The Lake Superior copper mines are spending money like water, but the cash is going into betterments which will enable the mines to produce copper more abundantly and more cheaply than ever before, when an era of low prices again dawns.

The New Electric Sinking Pump.

A pump for use in shaft sinking operations occupies a unique place amongst mining machinery. Such pumps are called upon to perform work under conditions entirely different from every other class of pumps and of most other machinery. While such a pump is expected to answer most of the requirements of any other good machine it must have peculiar characteristics in order that it may give satisfaction under the very trying conditions

under which such pumps must nearly always be used. While steam economy and smoothness in operation are very desirable features the requirements of a first class sinking pump are the following: *First*.—Absolute reliability of operation. *Second*.—Ability to pump both air and water. *Third*.—Small space, accessibility of vital parts, lightness, but designed to contain sufficient material to produce strength.

The illustration herewith presented shows the Jeaneville triplex electric sinker pump built with water proof motor, as manufactured by the Jeaneville Iron Works Co., Jeaneville, Pa., and Denver, Colo.

This sinking pump is the direct result of the great demand there is at the present time for the application of electricity to all kinds of mining operations. The makers claim for it the following characteristics and advantages: *First*.—It can be operated by an electric current, direct from a water power situated miles from the point of application. *Second*.—It produces no heating effect in the shaft, and the steam pipe is entirely eliminated. *Third*.—It is a most economical and efficient pump in power consumed. *Fourth*.—When the pump is stopped there is no waste of current, and when in use, current is consumed in the exact proportion to the work performed.

The construction of the pump as shown by the illustration is as follows. There are three single acting plungers operating from a common crank shaft with the crank pins placed at 120 degrees apart, the resultant action of these three plungers being the production of a continuous and constant stream to the column pipe and the reduction to a minimum of the shock and jar upon this pipe. The water cylinders are cast in one piece and are connected to the guides by hollow castings which form a vacuum chamber on one side and an air chamber on the other. The valves are of the well known type used in the Jeaneville steam sinker pumps and are easily accessible through hand holes at the face of the valve chamber. All of the gearing is machine cut and designed with sufficient strength to give a liberal factor of safety. All parts are completely accessible for oiling and inspection. The pump frame is designed to receive any make of motor which is adapted to this kind of work and which may be either direct or three-phase current. These pumps are built of different sizes and are guaranteed for one year against all breakages and repairs due to poor material, workmanship or design. Full particulars can be obtained by applying directly to the Jeaneville Iron Works.

Triplex Single-acting Electric Power Sinking Pump.
Jeaneville Iron Works Co., Jeaneville, Pa., U.S.A.

MINING PRACTICE

In Butte, Montana, Copper Mines. Methods Employed in the Various Operations.

Pumping Plant, Hoisting, Method of Repairing Ropes, Signaling, Boiler Plant, Blacksmithing and Sharpening Drill, Surface Works, Mine Accounts and Costs.

Written for MINES AND MINERALS by R. B. Brinsmade, B. S., E. M.

(Concluded from October.)

Pumping.—The Anaconda Company has its drainage so arranged that the pumps of the St. Lawrence shaft drain the Anaconda group and those of the High Ore shaft drain the Syndicate group. The other companies with groups of mines pursue a similar arrangement. The pumping installation of the High Ore and St. Lawrence shafts, which represents the latest practice, is as follows: the pumping is done by relays of approximately 500 feet each, and the station pumps are in duplicate, each having its own water column, and one pump being as a rule held in reserve. There were 3 new pumps put in in each shaft at the time of the adoption of this system in 1899. Each has a capacity of 500 gallons a minute at 600 ft. head, speed 50 revolutions per min., and a water end of $5\frac{1}{2}$ in. $\times$ 30 in. and an air end of 17 in. and 28 in. $\times$ 30 in. They are compound-duplex-plunger pattern, the water ends are built entirely of a special bronze, and there are no parts of the pump below the basal plate of its cylinders. They were made by the Dickson Mfg Co., of Scranton, Pa. The old pumps that complete the relays are of the same capacity but of Knowles make. The power furnished the pumps is compressed air delivered at 80 lbs. to 90 lbs. pressure, the pumps being designed for a pressure of 60 to 80 lb. at the throttle, the air is twice reheated by steam; first, before entering the high pressure cylinder and secondly in the receiver between the high and low pressure cylinders.

The first water columns used to resist corrosion were iron pipes lined with wooden staves; then the iron pipes were lined with $\frac{1}{8}$ in. sheet lead and the staves put inside this; the final solution of the problem was reached by using an iron pipe lined with $\frac{1}{8}$ in. sheet lead, which resists both pressure and corrosion. Fig. 30 shows a detail of this pipe, which has rendered unnecessary the wood lining, and has thereby decreased the friction of pumping by increasing the available cross section for the water, and has saved the expensive repairs of the stave lining. The joint is made by a special rubber gasket fitting into a groove, in the flange, Fig. 30, and the pipe is peened onto the cast iron flanges at each end.

Expansion joints placed every 200 ft. to 300 ft. along the columns permit of the easy replacement of worn lengths. At each pump station there is either a large brick cement-lined sump from which the pump draws, or a wood or natural rock tank above the pump. The suction strainers are either perforated bronze castings or perforated hollow cottonwood cylinders.

At the Anaconda group the mine water has leached the zone of the mine oxidized by the great fire, and it contains from 9 lbs. to 13 lbs. of copper per ton of water. This water is passed underground through sumps containing scrap iron, which reduces the copper contents down to from 2 to 4 lbs. to the ton before it reaches the pump sump. The residual copper is precipitated by large scrap iron vats on the surface.

At the Parrot mine the water is neutralized by lime placed in the tank which feeds to the pump, a stirrer driven by the pump rod keeping the lime agitated. The lime by reducing the acidity retards the precipitation of the copper on the surface, but it is undoubtedly the best method of saving the pumping apparatus at those mines where sulphuric acid and not copper is the corroding element. The water columns are kept clean by draining them occasionally as the ferruginous sediment does not harden. At the Parrot mine the pump at the 1,000 ft. level pumps direct to the

surface through a bronze column 5 in. internal and 6 in. external diameter and in 12 ft. lengths. The bronze lengths are peened on cast iron male and female flanges, and the flange joints are sheet rubber-gaskets. The pump itself is run by steam at 100 lbs. pressure and is duplex-compound-condensing, with jet condensers.

All the large pumping installations at the time of the writer's visits, with the exception of the above mentioned Anaconda plant, were run by steam taken down the shaft, the exhaust being condensed in the pump sump. Where the ventilation is deficient this large steam pipe has the advantage of making the shaft a strong upcast, and it is probably more efficient mechanically than the reheated air system for depths less than 1,000 feet. The condensation of the steam has the disadvantage of heating the sump water and thus causing a faster dissolution of the pumping apparatus.

Steel bailing tanks operated by the ore hoisting engine are used occasionally at all the large properties and at the Rarus mine they constituted the chief method of unwatering. This method keeps the shaft very wet. One pumpman on a 12 hour shift tends one pump station and often 2 or 3 stations in one shaft; for repairs or for working on the column pipe he has the help of the mine machinists and pipemen. Fig. 31 shows an efficient column-lifting device installed on the 600 ft. level of the Silver Bow No. 1 Mine. This apparatus enables the 400 feet of column pipe below the 600 ft. level where most of the wear is to be easily manipulated to replace a worn length.

The construction of this apparatus is as follows: There are two hydraulic cylinders *A* in each of which is a piston. A small steam pump, not shown in this sketch, forces black oil into the pistons *A* and these pistons then lift the eye-beams *B* which are supported on a pivot joint. The beams *B* enclose the column pipe *E* and by means of the pendant arms *G* and the cross piece *D* the column pipe is lifted when the beam arm *B* is raised.

FIG. 29.—DICKSON MFG. CO. COMPOUND DUPLEX PUMP, ANACONDA MINES.

At *F* is a square threaded screw that works in a nut attached to *B* and this enables *B* to be held at any required height when the column pipe is attached to it.

Hoisting.—Though the hoisting engines in the Butte district are of numerous makes, for the deep shafts they are practically all of the same type, i. e., first motion, with jaw or friction clutch and with flat-rope reel, the steam cylinders being simple. At the Blue Jay for an inclined shaft a round rope drum is used, as also at some of the shallower mines like the Berkeley and Silver Bow No. 3. On the large engines the valve gear is as a rule of the Corliss pattern with a Stevenson link motion for reversal. The throttle and relief valves, and the disc brakes are thrown by hand levers, but the reel brakes and the clutch are operated by steam power. The maximum rope speed is 4,000 ft. per minute, though at the Bell shaft a speed of 6,000 ft. per minute has been noted.

The brake blocks are made of cottonwood and the flat shape has been found more efficient than the wedge. The head frame sheaves for the flat ropes are 7 ft. to 10 ft. diam., and usually are made of cast iron with no liners in their grooves.

The ore in hoisting is usually counterbalanced as the station tender empties one underground station at a time of its cars. The load per trip varies at the Anaconda mine, which has one of the largest plants; the maximum load is, without counting the $\frac{1}{2}$ in. $\times$ 7 $\frac{1}{2}$ in. flat rope,

Double deck cage =	4,315 lbs.	
2 cars =	1,600	
2 cars of ore =	3,600	Total, 9,515 lbs.
5-ton skip =	5,550	
Ore in skip =	10,000	Total, 15,550

Grand total, 25,065 lbs.

This is handled by a 48 in. $\times$ 72 in. simple duplex hoist built by the Union Iron Works, San Francisco, Cal.

FIG. 30.

At the Never Sweat mine with 2-deck cages and with an 8-ton skip above them on one rope (at the Anaconda the skip is hung underneath the double deck cage), the cage and its load weigh the same, but

The 8-ton skip weighs 5,950 lbs.
8-ton skip load of ore weighs 16,000

Total, 21,950
Total cage, 9,515

Grand total, 31,465

This is without the $\frac{1}{2}$ in. $\times$ 8 in. flat rope. This load is handled by a 26 in. and 46 in. $\times$ 72 in. vertical duplex compound Corliss engine built by the Union Iron Works. The compounding has been a source of vexation owing to the consequent complication of parts and the difficulty of equalizing the load between the high and low pressure cylinders.

Most of the smaller mines use only a single or double deck cage, but the Colusa shaft is unique in having a cage of double width that carries 4 cars on its 2 decks. This large size has the additional advantage of permitting much of the timber to be lowered into the shaft flatwise, while the tramming horses can be lowered and raised for each shift, an unusual advantage for such animals.

The cages themselves are of structural steel and Norway iron throughout. Some two years ago an enclosed cage law was passed by the state legislature to protect miners, who if affected by bad air often fell off the open cages. The first attempt to obey the law was a sheet steel box, used at the Parrott mine, and shoved onto the cage proper on wheels; this was heavy and reduced the man-carrying capacity of the cage. The best device is a steel lattice work fixed to the cage, the ends of which can be folded up snug when not in use. This lattice is of great assistance in holding timbers on the cage so that which at first was thought a hardship has proved a blessing in disguise.

Not more than half the shift is usually consumed in hoisting rock; the balance being occupied in handling timbers and men. Though only adopted in Butte two years ago by the Anaconda Co., the skip presents great economy over the cage for rock hoisting. A skip saves weight and therefore power and time in hoisting, requires fewer station tenders, and most of all it saves cars; for by the employment of a shaft ore bin on each level cars are constantly in use and car men need waste no time waiting for empties.

The older mines in Butte have small shaft stations that retard the economical handling of cars for large ore production.

Care of Rope.—No doubt one reason for the preference for flat rope in Butte is the ease of inspection and repair. The safety dogs on the cages are tested once a week in the following manner: A 10 in. $\times$ 10 in. timber is put across the gallows frame at the base and the cage hung from it by manila ropes, the hoisting rope having been previously slackened, the manila ropes are then cut causing cage to fall, when dogs if in good condition will catch the cage.

Ropes constantly in use are tarred once a week, the cage being hoisted to the shaft collar and slowly lowered, the hot tar being applied meantime in a thin layer with a brush by one man on each side of the rope. The "tar" is a mixture of one barrel of pine tar to 20 gallons of beef tallow. While tarring, the ropemen inspect carefully the rope for flaws.

Every 8 months at the large producers, up to an interval of 2 years for the smaller mines, the flat rope is removed from the shaft and made over. There is always 1 and often 2 ropes in reserve for a shaft. An excess of 200 feet of rope above the shaft

FIG. 31.

FIG. 32.

FIG. 33.

depth is placed on the reel, so that the reel rope is still good while the part above the cage may be worn worthless.

The operation of making over a flat rope, is as follows: It is first unwound from the engine reel onto a wood reel A, Fig. 32, turned by power. The reel A is then removed to the rope house, a low building 80 ft. to 100 ft. long, and placed at one end on a frame, Fig. 32, arranged with power gears for winding in either direction. There is a similar empty reel B, on frame at the other end of the rope house. The following operations take place:

I. The rope is wound from A onto B and passed in the operation through a tank of raw naphtha to clean it.

II. The rope is wound back from B onto A, all the binding "thread" of the strands being cut while doing so.

III. The rope is wound back onto B, the binding threads being removed from the rope, the defective strands cut out and new strands spliced into their place.

IV. The rope is wound back on A and strands sewed together again by new binding thread as in making new rope.

V. The finished rope is then rewound onto B, passing in the process through a tank of hot tar.

The new flat rope is also made at the rope house by sewing together enough ropes to make the required width, $\frac{1}{2}$ in. or $\frac{3}{4}$ in. ropes of 4 coreless strands of 7 wires each being employed. The "thread" is 12 strands of No. 6 Norway iron, twisted, and used in 30 ft. lengths. A ropeman and helper can sew 80 ft. of $\frac{1}{2}$ in. $\times$ 5 in. rope in 10 hours; and a splice of a $\frac{1}{2}$ in. rope is effected in 15 minutes. The round ropes are also renovated when necessary, badly worn lengths being cut out, and new pieces spliced in their place, if the rope is worth it, cleaning by naphtha and subsequent tarring being performed as for flat ropes.

Hoisting Signals.—The engine telltale is commonly a large disc with a pointer turned by a bevel gear from the reel shaft; in addition the rope is painted white to indicate the collar of the shaft and other important points. There are 2 independent

signalling systems, the call for the station tender (or cage rider), and the system employed by the station tender to notify the hoisting engineer. The first system is either an electric bell, or an electric switch at each level that flashes simultaneously every light in the mine (the shaft conductors, to allow this, being three wires),* and the latter system is a manila bell rope in the shaft.

FIG. 35.

FIG. 34.

The Montana State Code of Signals is as follows:

2 pause 1 denotes	100' level	} Signals for electric system.
2 pause 2 denotes	200' level	
2 pause 3 denotes	300' level	
2 pause 4 denotes	400' level	
2 pause 5 denotes	500' level	
3 pause 1 denotes	600' level	
3 pause 2 denotes	700' level	
3 pause 3 denotes	800' level	
3 pause 4 denotes	900' level	
3 pause 5 denotes	1,000' level	
4 pause 1 denotes	1,100' level	
2 pause 1 pause 2,	station tender does not understand.	

1 stop if in motion	} Signals by bell rope.
1 hoist rock	
2 lower	
3 hoist men	
4 get ready to hoist men away from blast	
5 steam on	
6 steam off	
7 air on	
8 air off	
9 accident, then ring station signals	
3-2-2 send down drills	
3-2-3 send down picks	

After a man has rung station signal on the electric system, the station tender answers one bell, then if a man wishes to go up he rings once, if down twice, if station is only full of rock, the man does not reply.

Air Compressors.—All the large mines are provided with compressed air. The Anaconda and the Boston & Montana companies have central plants from which air is piped on the surface for thousands of feet to the various shafts. The Nordberg, Riedler, Rand, Ingersoll-Sergeant or Norwalk makes are used,

*See MINES AND MINERALS, Vol. XIX, page 486 for description of the flash-signaling system.

FIG. 36.

they are practically the same type, viz., cross-compound steam end with Corliass valves, and cross-compound air cylinders with inter-cooler. One of the largest is the Ingersoll-Sergeant compressor at the High Ore mine, the steam end of which is 30 in. and 56 in. $\times$ 60 in. stroke and the air end 30 $\frac{1}{2}$ in. and 60 in. $\times$ 60 in. stroke, non-condensing and running about 60 revolutions per minute.

The outlet valves are usually positive and the inlets of the poppet type, the fresh air being taken in from the outside of the building through a galvanized iron pipe. The air after compression is cooled at the Anaconda mines by passing it through a series of several old boilers placed outdoors, the compressed air circulating through the shell, while the atmosphere traverses the boiler tubes. Underground the air is reheated for the pumps and large hoists by reheaters in which the air circulates around a steam coil. Where steam is not available, I have seen reheaters consisting of nests of circulating pipes for the compressed air heated by oil stoves underneath. Each of the Anaconda Co.'s mines is provided with an automatic air pressure register, recording a curve that indicates the pressure for any minute of the day.

The air columns in the mine shafts are common sleeved and flanged, welded iron pipes with a branch at each working level. In the levels the air drills are connected to the air main by lengths of wire-wound rubber hose 30 ft. long.

Boiler Plants.—Though return tubular, locomotive and patent water tube boilers are in operation, the most improved practice uses the Scotch marine type, which is very efficient for the continuous steaming that is necessary in Butte mining practice.

A large battery of these marine boilers in 250 H. P. units is installed at the Anaconda, and another at the Green Mountain mine, each plant having a large self-sustaining steel stack. Fan draft is as yet unknown among Butte boiler plants and under present conditions would be of doubtful advantage.

The boiler feed water is from the city mains and no water purifier is necessary. A vegetable compound fed at intervals so loosens the scale that the boiler cleaner can easily scrape it out on his monthly visit. The boiler tubes are blown out every 24 hours by a steam hose, and the stack is also blown out by steam on those boilers with individual stacks. The boilers burning Wyoming slack, which is low in ash, have bar grates with slits for slack burning; the Belt and other coals rich in ash require the employment of shaking "finger" grates.

Feed Water Heaters.—The old type, Fig. 33, consisting of a wooden covered tank into which the exhaust steam entered above the surface of the water that nearly filled the tank and passed out through a wooden flue were leaky and inefficient. Mr. Ames, of the Anaconda Co., used an old boiler, Fig. 34, in a wooden tank. The exhaust steam entered through one end of the boiler shell and out through a flue at the top, while the feed water in the tank circulated through the boiler tubes, thus making a very good apparatus.

Steam Purifiers.—At the Silver Bow No. 1 mine, where the boiler plant feeds a large pump at the 1,000 ft. level and also the hoist on the surface, the condensed water all goes down the column to the pump station, where it is separated by a separator before the steam enters the pump. At the High Ore mine the steam is nearly all used on the surface, so that it is purified by a centrifugal separator before leaving the boiler house.

Repairs.—The Anaconda Co. has its blacksmith and machine shops at the Anaconda mine, with smaller repair shops at other mines. More complicated repairs are effected at the foundry in Anaconda, where small hoists and pumps, boilers and nearly everything else but the larger machinery is constructed. The Boston & Montana Co. has a large repair shop at its Leonard

mine, while a number of local iron works do necessary repairs for the other companies. Nothing in the machine shop practice is especially worthy of note.

Blacksmith Shop.—The wasteful practice of blowing the forges from a branch from the compressed air main, has been abandoned for the fan blast at most of the mines. A pipe cutter, drill press and sheet shear with the addition sometimes of a steam hammer, (made by the substitution of a hammer for a bit in a rock drill set vertically) are the tools in most of the small shops.

Machine Bits.—The X drill bits are made as follows: Fig. 35. A bit of Star steel is cut 18 in. long and then split at one end, the octagon steel shank of the required length is then cut with one end wedge shaped and welded to the Star bit. The table shows the sizes of machine bits.

FIG. 37.

Length of Drill, Feet.	Diam. Star Steel Shank, Inches.	Width Cutting Edge, Inches.
2 to 4	1 $\frac{1}{2}$	2 $\frac{3}{4}$ to 2 $\frac{1}{2}$
4 to 6 $\frac{1}{2}$	1 $\frac{1}{2}$	2 $\frac{1}{4}$ to 2
6 $\frac{1}{2}$ to 9	1 $\frac{1}{2}$	2 to 1 $\frac{1}{4}$

The sharpening is done by hand, as so far no machine has proved efficient for the purpose. The cutting edge of the bits is made at an angle of about 60 deg. and the wedge sides are rounded convex. The tempering for machine and hand bits is effected by reheating the bits after sharpening, to a visible red and then plunging them into water, giving a white temper untouched by the file. From each sharpening the bits lose $\frac{1}{4}$ in. to $\frac{1}{2}$ in. and even 1 in. if the edge has been broken. The average amount drilled in rock before dulling is 3 ft. A tool sharpener and helper can sharpen 200 machine bits in a 10 hour shift.

Hand Bits are sharpened to a bull point, Fig. 36, and the $\frac{7}{8}$ in. octagon steel has a cutting edge as in table below.

Length of Drill, Inches.	Width Cutting Edge, Inches.
16 and 22	1 $\frac{1}{2}$
28 and 34	1 $\frac{1}{2}$
40 and 46	1 $\frac{1}{2}$
above 46	1

In sharpening, the bit is hit in direction F and not G, Fig. 36, to produce a durable point. The loss for a sharpening is $\frac{1}{4}$ in. to $\frac{1}{2}$ in., if the edge is not broken.

Picks.—The picks are tempered by heating to a yellow and drawing out the point, then cooled in water to a blue by plunging with a quick removal. Each miner is allowed a sharp pick every other shift.

Carpenter Shop.—The shop at the St. Lawrence mine can be taken as an example. It is of structural steel and contains a rip saw for cutting wedges and ripping plank, a crosscut saw on a swing arm to cut poles and the square timbers to proper lengths for framing, and a framing machine for the square sets, made by the Anaconda Co.'s foundry, which by setting can cut at one operation the regular set tenons at one end of a timber. At

W. A. Clark's mines there is a framer built by the Denver Engineering Works that can frame both ends of a timber simultaneously. Special tenons and mortises have to be cut by hand tools.

Surface Works.—The old style was well illustrated by the Parrot mine as it was in 1898. The wood gallows frame was enclosed by a large wood structure containing divisions for the carpenter shop, the hoisting engine, the compressor, the boiler plant and the change room, as well as the ore shipping bins. This arrangement was with the object of having everything convenient to the collar of the shaft, it also sheltered the men in handling ore and timber and in going from the shaft collar to the change rooms, considerable advantages in the stormy northern climate of this district. The new practice is exemplified by the

St. Lawrence mine where the steel head frame is bare, and there are separate steel buildings for the hoisting engine, carpenter shop, etc. This new scheme permits of the freer movement of material and is practically fireproof. The head frames themselves, both of steel and wood, consist of 2 upright posts only, backed by 2 back braces, with ample lateral bracing for stiffness between the posts, and a framework to hold the shaft guides, extending up to the sheaves. This construction with 2 upright posts is the cheapest and strongest for Butte, as none of the frames have rock crushers connected with them, the crushing being done at the concentrators. Several of the wooden frames are 80 ft. from the base to the center of the sheaves, the easily obtainable Oregon fir making this huge construction easy. The largest steel frames are those at the High Ore and Diamond shafts, built by the Gillette-Herzog Co., of Minneapolis, Minn., they are 100 ft. to the center of the sheaves.

All the large mines are provided with switches to their ore bins and boiler houses by either the Great Northern or the Northern Pacific systems, so that the whole district is a vast network of railroad tracks.

Change Rooms are a very important mine adjunct for the health of the men, where in winter there is often a difference of 80 degrees Fahrenheit between underground and surface temperatures. They are provided with steam pipes for drying clothes, sinks for washing, and the Leonard mine has even separate lockers for each man's clothes.

Ore Bins.—Where cars are used they are run direct from the cage to the shipping bins and dumped. The skips at the High Ore mine dump direct into the shipping bin, while at the St. Lawrence mine, they dump into a small wooden bin, whence the ore is fed into a 5-ton car and pulled by a mule to the shipping bin, 100 yds. distant. At the Anaconda mine the skips dump into a bin on the 100 ft. level, whence a mule drags the 5-ton transfer cars above the Never Sweat mine shipping bins through an underground tunnel. Fig. 37 shows the arrangement in the Anaconda shaft. The shipping bins themselves present various types of timber construction, Montana fir or pine. The favorite gate is the one raised and lowered in a vertical groove by rack and pinion. The bins have often steel linings of sheet steel or old rails.

In Fig. 37 *F* is the lower deck of the double-deck cage. The skip *E*, which holds 5 tons of ore and is hung from *F*, is self dumping. During hoisting the skip is held vertically by a hook attached to the frame *L*; this hook is struck upon reaching the trip *H* and the roller *K* on the side of this skip then runs out on the track *D* and dumps into the bin *B*. This track *D* is made up of a bent angle-iron bolted to steel plates and fastened to the sides of the hoisting compartment. The parts *H*, *D* and *K* are duplicated on the opposite side of the skip *E*. The bin *B* discharges into the 5-ton car *C* through a vertical sliding ore gate which is worked by a compressed air cylinder as shown. The car *C* is drawn through a tunnel about 1,000 feet by a small mule and dumped above the railway shipping bins. Timber and men are hoisted to the surface on the cages and the ore can be also hoisted to the surface on the cages in cars if it is desired to increase the capacity.

Supplies.—The Anaconda Co. has a number of subsidiary departments to furnish supplies. A large warehouse at the Anaconda mine furnishes vast quantities of mine supplies, kept constantly on hand, in the charge of a special clerical force. The hardware department that has a retail store on Main St., also supplies the mines. The lumber department with yards in South Butte is supplied by its own mills located in various parts of Montana. The ore is shipped on the company's own railroad, the Butte, Anaconda & Pacific, to the smelter in Anaconda, in which town is also located the company's foundry department already mentioned. The coal mines at Belt, Montana, and at Diamondville, Wyoming, supply the various mines with coal.

The Boston & Montana has nearly as complete an equipment as the Anaconda, but the smaller companies depend chiefly on the merchants for supplies.

Mine Accounts.—At each large mine there is a timekeeper, and at the mines of the Butte & Boston the system is as follows: The day shift men are checked off by the timekeeper going on shift at 7 A. M. and coming off shift at 5:30 P. M., the night shift men going on at 6 or 7 P. M. This record is kept in a time book and each month a time sheet is made out from it and sent to the main office of the company down town. The labor time is also daily divided by this timekeeper into ore breaking, tramming, timbering, hoisting, pumping, boiler room, repairs and alterations, prospecting, miscellaneous, on a special sheet, and sent to the main office for computation, the summation of these sheets forms a check on the monthly time report. He also orders and receives the necessary supplies and records in which account they were used, and from his supply book makes out monthly a separate sheet for each account which he sends to the main office, and by these the supply expense is not only quickly apportioned, but a check

is obtained on the invoices of supplies that have been received. The timekeeper also sends in a daily report of the ore and waste hoisted and the ore shipped, with the locality whence the rock came. All the general accounts and ledgers are of course kept in the main office in the Lewisohn Building down town.

Mine Numbers.—To facilitate these reports of the timekeeper, each working in the mine is numbered by a wooden sign hung up in it. The system is as follows: All the working numbers are for any level between the corresponding hundreds for that level's number, thus, C No. 511 would mean chute No. 11 on the 5th level, all the numbers on the 5th level being between 500 and 600. Each new drift or stope being given the number between 500 and 600 next following the last one in use. At the Pennsylvania mine the 100 numbers of a level are separated into two parts, one to represent the west and the other the east side of the mine, and this as a further amplification would probably be followed in all the mines if they were to be renumbered.

Mine Labor.—At the Parrot mine during the writer's engagement in 1898 an average production of 400 tons of shipping ore was maintained and the list of men per 24 hours and their rate of wages and duties were as follows:

1 mine superintendent (part of his time only) @	\$10.00	2 compressor engineers	4.00
1 timekeeper (part of his time only) @	3.50	2 firemen	3.00
1 mine foreman	6.00	2 wood passers	3.00
1 surveyor and helper	5.00	1 boiler cleaner (one-third of his time only)	3.00
2 shift bosses	5.00	1 boss machinist	5.00
2 pumpmen	4.00	1 pipeman	4.00
3 station tenders	3.50	1 ropeman and helper	4.00
1 blacksmith and helper	4.50	1 head carpenter	5.00
2 tool sharpeners and 2 helpers	3.00	2 carpenters	4.50
1 teamster	3.00	1 carpenter's laborer	3.50
4 top carmen	3.00	1 powder and tool man	3.50
3 hoisting engineers	4.00	6 timbermen, at	3.50
		170 miners, carmen, and shovel-	
		ers	3.50
		1 night watchman	3.00

As Butte is a strong union town the men have uniform hours of work, viz., 10 hours day and 9 hours night shift with an hour less per shift on Saturday, 7 days per week being worked. The men on 8 hour shifts were the hoisting engineers and station tenders, and those working 12 hours were the pumpmen, compressor engineers, and firemen. The carpenters worked 9 hours.

The high wages attract to Butte the best artisans and laborers in their respective spheres in the country, and as there is always a surplus the companies have usually no difficulty in finding good men. The unions place no restriction on the hiring and discharging of men and the new comers in the camp usually work for some time before joining the union. The only points upheld are the rate of wages and the number of hours per shift worked, and for many years there has been little friction between the unions and the operating companies.

Sunday work is pursued at the mines by all the companies, except those of the Bigelow syndicate. It has been found by the latter that, aside from any religious or social reasons for a weekly rest day, it is more economical for the companies.

Hospital.—A dollar a month is deducted from the wages of each employe for the hospital fund. The sums thus obtained are paid by the mining company to one of the private hospitals, of which there are several owned by physicians or by Roman Catholic Sisters, and each man receives from the selected hospital free surgery and board when disabled.

The Bigelow Companies have also a system of accident insurance by which each employe by paying a certain per cent. of his monthly pay receives during disability half of his accustomed wage.

Working Cost.—The cost is really the most important part of the mining operations from a business standpoint and is usually the most difficult thing for outsiders to obtain, while company officers are seldom free to disclose such figures.

The following figures of working cost for the Anaconda Co. appeared in the "Rossland Miner," Oct. 15, 1899:

Production of ore, 1,459,249; cost per ton, \$3.94; total, \$5,745,784.29.
 Tons concentrated, 1,459,249; cost per ton 77 cents; total, \$1,124,508.96.
 Concentrates smelted, 500,000 tons; cost per ton, \$6.40; total, \$3,200,875.
 Copper converted, 62,358 tons; cost per ton, \$17; total, \$1,073,988.55.
 Product refined at Anaconda, 30,153 tons; cost per ton, \$20; total, \$603,123.77.
 Product refined at Seaboard, 32,105 tons; cost per ton, \$30; total, \$963,891; grand total, \$12,964,614.

These figures are all rather high compared with the table of the Boston & Montana costs following. The reduction works are especially inefficient, all the costs of reduction, except the refining at Anaconda, being excessive, and these costs are due to inefficient machinery and badly arranged buildings for economical handling of material. These defects will be remedied in the vast new reduction works to be soon erected in Anaconda, as will also the large loss of copper, especially in concentrating, that takes place at the works now in operation.

The figures below were given by Mr. Maginnis of the Montana Ore Purchasing Co., as working costs of the Boston & Montana properties in 1898.

Cost of mining (estimated) per ton.....	\$2.00
Freight to Great Falls from Butte	.75
Concentration from 2½ to 1, per ton ore.....	.40
Calcination (reduction of weight 15%) per ton concentrates.....	.75
Smelting per ton of concentrates.....	2.55
Smelting per ton of ore.....	1.02
Smelting per ton of matte.....	3.00
Converting per pound of matte.....	.005
Electrolytic refining, per pound of blister copper.....	.01
Freight to New York, average per 100 lb. of copper.....	.70
Insurance, average per 100 lb. of copper.....	.05
Selling commission, Lewisohn Bros., 2½%.....	
Total cost of producing 1 pound copper, in New York.....	.0545
The loss allowed in concentration is set at 20%.....	
The loss allowed in smelting is set at 10%.....	
<i>First-Class Ores.</i>	
Smelting after calcination per ton of ore.....	\$2.55
Total cost per pound up to process of converting.....	.0134
Total cost per pound for treatment of 25% ore.....	.0384

The figures of *mining* cost, with which this article has alone to do, given for the B. & M. Co., are probably the minimum to be achieved under present prices of labor and supplies. As the mines grow deeper this cost will show a gradual increase, which, however, can be rendered almost imperceptible by the improved hoisting and pumping devices that have been lately introduced to provide for these items of increased cost from deep mining.

It is an interesting fact for the sociologist that the mining and smelting costs in Butte are actually less per pound of copper produced than in nearly any other district in the world, in spite of the highest average rate of wages paid at any copper camp. This is not only due to the high tenor of the ores, but largely also to the fact long ago noted by economists, that with a high rate of wages and a consequent influx of the most intelligent workmen, there is every incentive to equip a productive enterprise with the latest devices in labor-saving machinery; so that by the aid of this machinery, which is scarce in low priced labor districts as a rule, the labor cost per pound of product is much less than in those places using low-priced hand labor.

With the vast bodies of ore in sight in the Butte district, and the great demand and high price for copper as well as from the amicable relations between capital and labor, the outlook for the camp is assuredly a very bright one.

CARE OF MAPS.

How They Should Be Kept—Some Frightful Examples of How They Are and Ought Not to Be.

Written for MINES AND MINERALS, by L. C. M.

An engineer generally regards his maps as a thrifty housewife does her articles of furniture. Anything that can be done to lengthen their life and keep them in good condition is to be commended. It takes a man who has spent several weary weeks on the construction of a map to know how to handle it properly. He has the proper respect for the amount of labor entailed if not of the monetary value of the time consumed, while any one who has been forced to do work on a dirty broken map has it vividly impressed on his memory that a map can not be handled too gently. The life of the maps of any coal company is reduced one-half by the rough usage they are subjected to. This seems to be putting it rather strongly but from an experience of a number of years the writer is inclined to believe it is a conservative estimate. This rough usage of maps comes, in the majority of cases, from the men from whom it would be least expected. That is from the officials, the chiefs of the various departments, the superintendents, men who in nine cases out of ten have advanced from engineer corps and are perfectly familiar with the labor and expense entailed in the making of the maps. They know from personal experience the difficulty and annoyance of trying to do accurate and neat work on a broken or dirty map. With their advancement they seem to forget all this and seemingly have no regard for the handiwork of their successors. It seems as if this was the way the official shows his superiority, his authority to do as he pleases. To cite a typical example. A superintendent comes into the engineering office. He wants to see a map of a particular locality and wants to see it quick. It is brought from the vault. He grabs it. Slams it down on the table. Grasps one end of it near the middle and flings the rest from him. As it unrolls drops a weight on it. He may be a little dusty and his hands dirty but that doesn't make any difference. He flings himself on the map, takes a blunt-pointed pencil of the nondescript variety and proceeds to make a few free handed sketches with possibly an odd calculation or two on it also. Now this man should be perfectly well aware of the damage he is doing. He evidently realizes the

inconvenience he is putting those to who have the mapping to do. Yet he regards his time as being of so much value as to make it perfectly permissible for him to handle the maps so roughly. A few moments of his time—barely a full minute would be required to handle it properly—is worth several years of the maps life. Is worth several hours of some one's time engaged in removing his sketches, calculations, etc., that could as easily have been made on scratch paper and the removal of finger prints or the impression of dusty clothes which but a moment of his valuable time would also have rendered unnecessary. His treatment of the map has a demoralizing influence on all who have witnessed his actions. Their respect for a map is lowered to his estimation of the same, while their treatment of the map will be patterned after his. But the most demoralizing effect will be on the man who has made or is making the map. He has seen it grow under his own hands from a blank piece of paper to the valuable map it now is. He regards it as something of his own, has taken the greatest pains to make it accurate and neat and to keep it clean. Then to see it handled in the disrespectful manner in which it is, maltreated and smudged, finger prints and lead pencil marks on it. He feels that he could hardly be less shocked if the same grimy hand had been placed on the bosom of his shirt. But the worst is he can never regard his map with the same pride he did before. On seeing how his superiors have treated it he becomes less careful in his treatment of it. Not only does it suffer from this lack of care, but what is far more important, less attention is paid to the neatness and accuracy of any additional work put on it.

With the best of care maps will soon show the effects of wear they are subjected to; their edges become frayed and cracked, the ink dim, the paper turns yellow or rather a dirty brown. The frayed edges can be obviated by binding the map. The best form of binding in the writer's experience is a folded gummed binding of some tough cloth, which comes already prepared only requiring moistening to be put on the map. If put on neatly it adds to the appearance of the map, fully protects the edges, and also at the same time protects the work on the map itself. For it forms a slightly elevated track for the map to roll and unroll on, causing less wear or rubbing of the inked surface.

The best possible way to lengthen the life of a map is by means of a tracing of the same, which should be used as much as possible in place of the original. An accurate tracing kept fully up to date will answer the purpose of the original map in nearly all the cases requiring its use. In case of consultation by the various officials it does just as well if not better on account of the less bulk to handle. Minor details and small surveys can be plotted directly upon it. Fifty per cent. of the wear and tear of a map will be taken off of it by the proper use of a tracing. The making of a new tracing bears no comparison to that of making a new map.

A map should as much as possible be in charge of but one man. If he puts on all the work and knows that he is responsible for it all, greater care and neatness will be exercised in putting it on. He will take greater pride in the map, knowing it is all his own handiwork, and not a patch-work of two or three indifferent draftsmen, and the condition of the map will reflect this pride. There is nothing so demoralizing to a map as to have three or four men do work on it promiscuously. Let one man plot the surveys. Have the tracing immediately brought up and it will only be necessary for one man to handle the map. The writer vividly remembers a particularly shocking example of disregard shown a map, which occurred in his apprentice days. It was done by the president of the company and for that reason was made doubly impressive. One of the first lessons impressed on the writer's mind was that a map was something almost holy, only to be approached with the cleanest of hands while a plentiful supply of newspapers protected all surfaces liable to be damaged by contact from the clothing. It was during the absence of the chief engineer, when word was sent up to bring down the map of No. — mine. It was here where the first blunder was committed, instead of taking the tracing of the mine, the message was taken literally and the map itself taken down. The table in the president's room being too small to accommodate the map, he took it and dropped it on the floor (a very dusty matting being on the floor), a grimy handed mine foreman held one end while the president unrolled the map with his foot; and then got on it with his feet, walked all over it pointing out various details with the point of his cane. I have heard of the various impressions left by feet on different substances, the poet tells us a little about it, but the aforesaid poet had never tried to remove No. 9 footprints from a map when he wrote that poem. I spent a day at the job with ill success. Some of those prints were visible for years after. A tracing was made of one of them, and including a detailed account of the occurrence. This was labeled and hung up in the office, while underneath, heavily underscored, was a threat of the most direful punishment of any who tried to follow in the footsteps of the president.

ELECTRIC WIRING IN MINES.

The Difficulties Which Must Necessarily be Met, and Some Means of Reducing the Dangers of Faulty Insulation.

Written for MINES AND MINERALS, by Alton D. Adams.

In but few other places are so many conflicting requirements to be met, as to electric wiring, as in mines. Distances over which the electric energy must be distributed are often so great that comparatively high voltages are necessary to economy in the copper conductors. The higher the voltage of circuits, the greater the necessity for a high degree of insulation, and yet the conditions in mines are such that most wires must be run bare. If wires of comparatively high voltage must be used without an insulating covering, it is desirable that they be erected beyond the easy reach of men and horses, but the head room in mines is often such that this precaution cannot be taken. The large amount of moisture present in a mines renders it very difficult to maintain any high degree of insulation on wires unless they have a covering of rubber, and the sulphur present in the moisture of many mines, especially those of coal, rapidly ruins rubber insulation. The result is that circuits of comparatively low pressure are frequently run with bare wire. A moderate amount of insulation from the earth is obtained at the points of support, by using only large porcelain or glass insulators for the attachment of the wire. Care should be taken to have the wires touch nothing save their insulating supports, and porcelain tubes are convenient in some cases for this purpose, where the sides or ceilings of passages are uneven. Such tubes should also be used in every case where wires go through partitions. With bare copper circuits, in mines where there is much moisture, the most careful work will not ensure a high resistance to earth, because of the films of moisture that collect on the surfaces of the porcelain and glass. While this moisture on insulators is not usually sufficient in amount to cause any serious loss of power, it may well cause a severe shock to one who makes a single contact with the circuit, if his body is also in electrical connection with the ground. The existence of these conditions points to the conclusion that all distribution circuits in mines, should be operated at a voltage that is not ordinarily dangerous to the life of man or beast, so far as possible.

Three kinds of electric service must usually be provided for in mines, lighting, stationary motive power, and hauling. The voltages of circuits for these purposes are apt to vary somewhat according to the kind of electrical supply adopted. The only satisfactory motors available for traction purposes are those of the direct current type. Such motors may be operated at any voltage within wide limits, but the prevailing pressures for railways in mines are 250 and 500 volts. Stationary motors of the direct current type are usually operated at 220 or 500 volts to correspond with generators for incandescent lighting or with the traction system. Satisfactory induction motors operated by two or three phase alternating currents, are now in use. These motors are usually supplied by transformers distant not more than a few hundred feet, and there is therefore, no reason for a voltage higher than 250 on their local circuits. If incandescent lamps are supplied with direct current, the voltage on the two wire system must be about 125 or 250 to correspond with those of lamps. In case the three wire system of distribution is employed for the lamp circuits, their maximum pressures will be twice those just named, or 250 and 500 volts, according to the pressure required at lamps. Lamps on alternating current circuits are usually supplied by comparatively near transformers, and there is slight incentive to use maximum pressures greater than 125 volts on the two wire or 250 volts on the three-wire system.

With these facts, as to the general requirements and limits for electric pressures in mine work, in mind, expedients for greater safety and convenience of operation may be considered. The standard pressure for electric street railway lines all over the country is 500 to 600 volts. The Edison three-wire system of distribution, as extensively used by central stations has very generally employed a pressure of about 250 volts between its outside wires. Experience, gained from these two extensive classes of circuits, has demonstrated that 500 volts is sufficient pressure to readily kill a horse and even a man, when a good contact with both sides of a circuit are made. On the other hand it has been equally well demonstrated that 250 volts will not kill a man under any conditions as to contact that are at all likely to exist in practice, but this conclusion does not follow as to a horse. In mines, where both men and mules are liable to make contacts with live circuits of bare wire, it seems highly desirable that their voltages be limited if possible to 250, and especially that the difference of pressure between either side of any circuit and the ground be not greater than this amount. As above pointed out, there is seldom any good reason for a pressure of more than 250 volts on the alternating current circuits for incandescent lamps

and motors in mines. Direct current distribution to both incandescent lamps and stationary motors may be carried on in mines at maximum pressures of either 250 or 500 volts, with corresponding possible differences of pressure between any wire and the earth of 125 or 250 volts respectively. This result is reached by the expedient, very generally adopted in Edison city systems, of grounding the third or so called neutral wire of the three wire system. Accidental contact is seldom made with more than one electric wire at the same time, and a shock, from one side of a three wire system with a grounded neutral, is given with only one-half of the maximum voltage. The conditions as to the insulation of circuits in mines, as pointed out, are such that the maker of contact with one side of an electric circuit is quite apt to receive the maximum pressure of the circuit unless it has a grounded neutral. The moderate pressures necessary on transformer circuits and the grounded neutral of three wire systems thus greatly reduce the dangers from circuits for lighting and stationary motors in mines.

Most dangerous among electric systems in mines are the trolley or railway circuits. The wires leading to lamps and stationary motors may be grounded, so that a person touching either wire will receive the maximum pressure, though this is not usually as much as 500 volts. There is however some chance of escape without injury from accidental contact, since the ground connections on the lamp or stationary motor circuit may be slight, or the electric pressure of the circuit may be low. One side of the street railway system of electric conductors is however permanently and securely grounded by the use of the track as all or a part of the return circuit. Any one touching the trolley or the uninsulated feed wires is therefore subject to the full difference of pressure between the two sides of the system, if they are in electrical connection with the ground or rails. In places where the pressure on the electric traction system in mines is kept at about 220 volts the probable damage to men or animals is very slight, but repeated and serious injuries have occurred in mines where 500 volts are employed. The very material incentive to the use of the 500 volt traction system is the fact that, compared with a system having 220 volts as a maximum, it saves 75 per cent. of the necessary copper in conductors, all others factors remaining constant. This consideration is of especial weight in those instances where distances are so great that the relative amount of the investment for copper is in any case large. Fortunately however there is a means, though it has not been generally employed for the purpose, by which the advantages of the 500 volt traction system in mines can be retained and at the same time the pressure between the trolley or any of its feeders and the earth or rails limited to 250 volts. This result is reached by applying the three-wire system, long successfully used for lamp and stationary motor circuits, to traction circuits in mines. For this purpose two trolley wires should be used, one connected to each side of the traction generator, or to the free sides of two generators in series. If only one generator is used, the conductors from the rails to the power station should be connected to a small dynamotor, designed to keep the rail pressure halfway between that of the main terminals. If two generators are used in series for the traction lines, then the rail conductors should be taken to their common connection. On a double track road, one trolley wire, representing one side of the system, should be erected over the center of each track, but for a single track road one trolley may be located about over each rail. In this latter case trolley poles should be mounted near one side instead of on the center of cars or locomotives and about one half of them take current from each trolley. This arrangement evidently makes the rails the third or neutral wire of a three-wire system, and any accidental contact between either trolley wire and the rail or ground is exposed to a pressure of 250 volts, when the voltage between the two trolley wires is 500. Contact through accident with both trolley wires at the same instant is improbable, and the three-wire thus offers a decided increase of safety over the two-wire system with 500 volts between trolley and rails. While the low pressure circuits for lamps and stationary motors are quite safe as to their own voltages, there is danger from another source in those cases where these circuits run from alternating current transformers that are supplied by high pressure lines. This danger arises from the fact that a ground connection at any point on the high pressure circuit and a cross between the high and low pressure circuits inside the transformer or elsewhere, exposes one who makes contact from the low pressure to the earth at any point to the voltage of the high pressure circuit. Such an accident would probably result fatally, as the primary alternating lines usually operate at pressures as great as 2,000 or 3,000 volts. This danger can be very largely averted by a substantial and permanent connection between one wire of every secondary circuit and the ground.

If the secondary circuits from transformer are on the two wire plan, either side may be connected to earth, but if they are

run three wire the neutral should be so connected. The connection to ground when properly made is of much lower electrical resistance than the body of a man or animal and the only damage likely to result from a cross between the primary and secondary circuits is a blowing of fuses. The high pressure primary lines to transformers should be kept out of the parts of mines in which work is going on, as far as possible. Rubber covered wires, cotton braided and with a sheath of lead on the outside seem to be the best material for the primary circuits. Where high pressure wires are exposed to mechanical injury, as in vertical shafts, the rubber and lead covering just mentioned should be used and a substantial iron pipe erected, into which the leaded wire is subsequently drawn. It is not necessary to have any lining of insulation for the iron pipes, or to supply insulating supports for it.

Constructing Mine Cross Sections With the Aid of the Pocket Slide Rule.

Written for MINES AND MINERALS, by Leo Gluck, M. E., Butte, Montana

The mining engineer and geologist in the construction and study of cross section of veins by vertical planes of section which are not at right angles to the strike of the vein and therefore do not show the true dip of the vein in the cross section, but instead show an apparent dip, must solve the problem of finding the dip of the line of intersection of a vertical plane (section plane),

whose strike is known, with an inclined plane (vein plane) whose strike is also given.

The converse of this problem where the dip of the line of intersection is known from the cross section, and knowing the strike of the section plane and also the strike of vein plane from the plan map, to find the true dip of the vein.

In Fig. 1, ABC represents the strike of the vein plane $ABC'G'F'D'$, its true dip being $FB'F'$ or $B'F'B' = d$. DBE represents the strike of the vertical section plane $DBE'E'B'D'$ then EBC or $E'B'C'$ or $F'D'$

FIG. 1.

$B' = \beta$ or the included angle of the strike directions.

The problem to be solved is the following: Given the direction of strike of the vertical section plane and of the vein plane and thereby fixing the angle β , the vein plane having a true dip of " d "; to find the "apparent dip" angle " x " of the intersection of the two planes in question.

From Fig. 1, the trigonometric solution is as follows:

$$(1) \quad \tan d = \frac{B'F'}{B'B'} \text{ or } B'B' = (\tan d) B'F'.$$

$$(2) \quad \tan x = \frac{B'F'}{D'B'} \text{ or } D'B' = (\tan x) D'F'.$$

Combining (1) and (2),

$$(3) \quad \tan x = \tan d \left(\frac{B'F'}{D'F'} \right).$$

$$(4) \quad \text{But } \frac{B'F'}{D'F'} = \sin \beta;$$

therefore substituting (4) in (3)

$$(5) \quad \tan x = \tan d \sin \beta.$$

If β and x were given to find the true dip d formula (5) is transposed into (6) $\tan d = \frac{\tan x}{\sin \beta}$

The value of the simple formulae (5) and (6) in the solution of problems in question is usually not made use of for the reason of the time required in looking up the natural sines and tangents, their multiplication or division and the finding of the angle corresponding to their product or quotient; or if logarithms are used a corresponding time is required for the solution.

The writer has found that the ordinary "Mannheim" pocket slide rule can be very advantageously used for the rapid and accurate solution of these problems, even though requiring extra

movements, which, however, can be quickly performed, due to the fact of its being graduated for other purposes than called for in these problems. The writer by especially designing the slide rule, as described later, has reduced the number of movements and therefore also the time for the operation of the multiplication of a sine by a tangent; or the division by a tangent.

The top of the slide BB Fig. 2 is graduated to the right for sines to 90 degrees and correspondingly the natural sines to 90° are immediately above on the rule AA .

The bottom of the slide CC is graduated to the right for tangents to 45°; and can, for angles greater than 45°, be read to the left; correspondingly below on the rule DD the natural tangents of the same.

The operation of the solution of $\tan x = \tan d \sin \beta$ is as follows:

First bring the fixed indexes of the rule and slide together, then on BB find the sine given and mark the same by the movable index, reading the same off on AA .

Find the corresponding number on DD and mark the same by the movable index, then move the slide CC say to the left until the fixed index coincides with the movable index; move the movable index and read the given tangent on CC without disturbing the movable index. Bring the slide into its initial position of having the fixed indexes together, then read off the required angle on the Tangent scale on slide CC marked by the movable index.

If the given tangent is greater than 45°; subtract the same from 90° and the operation is then as follows:

Bring all the fixed indexes together and as before transfer and fix the natural sine reading to DD by the movable index. Read the tangent subtracted from 90° on the slide CC , making it coincide with the movable index. The final reading is obtained on CC where CC coincides with the right fixed index of DD .

The transferring of the sine from BB to AA and then to DD can be avoided by graduating the slide rule especially. Instead of the graduations reading natural tangents on rule DD the same can be graduated to read the natural sines corresponding to the tangent values

on CC . The problems then in question require only the slide graduated for tangents on CC and for sines on DD thereby saving the transfers from BB scale to AA and then to DD beside eliminating the use of AA and BB scales entirely, thus simplifying the slide rule for the special purpose.

FIG. 2.

Alabama Coal Production.

As Alabama is the fifth largest coal-producing State in the Union, and as its production increased from 5,893,770 tons in 1897 to 7,484,783 tons in 1899, with an estimated production of 10,000,000 tons for 1900, it would seem that there will be not only a sufficient amount produced to supply all demand in the State, but a generous product for export. Such was the case up to within the past two years, but in that time Alabama had forged to the front as a great iron-producing State, and the tremendous demands for iron in all of its forms has given such an impetus to the iron industries as to cause an unprecedented demand for coal for coking purposes, and any surplus that previous years may have shown has vanished. The opening up of thousands of coke ovens has made necessary also the opening up of new coal mines in order to supply this increased demand for coal by the iron industry alone.

In addition to these, many large manufacturing plants have been erected within the past year, not only in Alabama but in sections of other States near the coal fields, and extensive additions have been made to old plants. All of these depend on Alabama coals for steam purposes, and have added largely to the State production. In Alabama alone 52 cotton mills are now in operation, with several new ones in course of erection, to be completed by October 1, 1900.

Another factor is the increased demand by railroads, made necessary not only on account of the building of new lines, but by the increased commerce extended to them from the different industries, as well as from the general building up of the State.

Though the receipts at Mobile exceeded those of any previous year, yet the bulk of the coal has been barely sufficient to supply the home demand, leaving only 4,770 tons to be applied to export orders, which orders have aggregated several hundred thousand tons. Outside of exporting coal, Mobile's business consists largely in supplying steamers with bunker coal. This branch of the trade in the past year has shown a considerable increase, 372 steamers having entered the port of Mobile in six months.—*Twenty-second Annual Report U. S. Geological Survey.*

THE WORLD'S MINERAL PRODUCTION.

THE accompanying illustrations, which are reduced from large diagrams prepared by Mr. E. W. Parker, Statistician of the United States Geological Survey, Washington, D. C., for the Paris Exposition and reproduced through his courtesy, show graphically and very strikingly the preeminent place occupied by the United States as a mineral producer. In these diagrams the height of the Eiffel tower is taken as the measuring stick, and with this enormous measuring stick immediately before the eyes of all visitors to the Exposition the immensity and magnitude of our mineral resources have undoubtedly been most powerfully and strikingly impressed upon all foreign nations.

At the present time the greatest interest naturally centers in the coal production, and although the output of England for the year 1899 was not available when these diagrams were made up it will be remembered that these figures which have already been printed in detail in MINES AND MINERALS show the United States to have been an even more preeminent leader during the year 1899 when for the first time they passed Great Britain as a coal producer.

Having once assumed this leadership in coal production it seems scarcely possible that the position will be given up, at least, for many years to come, for as we have previously pointed out in editorials in the April and July issues of MINES AND MINERALS the rate of increase in coal production upon the part of the United States has been so very much more rapid than in all the other countries that there is little possibility that Great Britain will again assume the lead.

The principal theme for discussion now is to what extent the United States will enter upon the European market. The English mining journals are trying to bolster up the spirits of the English coal producers by depreciating the value and extent of the amount of coal exported from the United States for some years past. To be sure this amount has been small compared with the much larger amount exported from England, but if the present activity continues and if the market for coal holds out as it gives promise of doing, there will undoubtedly be a great increase in exports. There are two reasons why this has not occurred heretofore. First, the enormous demand for coal within our own borders has absorbed the surplus. Second, and chiefly, the lack of transportation facilities. This second reason cannot be immediately remedied, of course, but if it were not for the fact that at the present time a great number of the ordinary ocean carriers have been taken from other regular trade by the war interests in South Africa, China and the Philippines, the export of coal from the United States during the year 1900 would undoubtedly have been a very greatly increased quantity.

This subject of transportation is being carefully investigated by some of the largest producers and transporters of bituminous coal, as well as by the individual anthracite operators, and if as a result of this investigation it can be shown that the European market will probably be a constant one, the lack of transportation facilities will undoubtedly be quickly remedied.

The problem of the transportation of iron ores from the Lake Superior mines to the East was solved through the invention of the whaleback, and this, together with the wonderfully economical handling of both ore and coal, has greatly reduced the cost of carrying these commodities through the great lakes. If the demand is sufficient, it is quite probable that some form of ocean whaleback or similar device will be brought out and a new method of transatlantic transportation thus furnished. It is matter of history, and not simply American pride and boasting as some would have us think, to say that every similar commercial and industrial problem of this kind has been promptly and successfully met, and it seems only reasonable to argue and to believe that this bridge of costly transportation will be crossed and put out of the way as soon as there is a real necessity for its being done.

The position of the United States as a producer of pig iron is

very well shown by the second portion of the diagram and when we remember that it was only in 1890 that we first passed Great Britain in this respect, the rapid increase which has since been made will be better appreciated, and in this item the end is not yet, for the steel works of the country are constantly getting into better form for increased production.

In petroleum we must yield second place to Russia, but compared with the rest of the world our barrel is seen to be of very much greater capacity than that of the barrels of all countries of the world excepting Russia.

number of years, we have to bow the knee to both Africa and Australasia. It is a striking fact that these three greatest producers are all English speaking countries so that the honor of producing nearly all of the world's wealth is kept within the family, for the amount produced by all other countries is very small compared with that produced in Africa, South Africa, Australia, Canada, and the United States.

Probably the most striking table is that of the total mineral production, which shows the United States to be preeminently the mineral producer of the world. In the light of the increase

WORLD'S PRODUCTION OF COAL.

WORLD'S PRODUCTION OF PIG IRON.

WORLD'S PRODUCTION OF PETROLEUM, 1898.

WORLD'S PRODUCTION OF COPPER AND LEAD. Figures indicate pounds.

WORLD'S PRODUCTION OF GOLD AND SILVER, 1898. GOLD. SILVER. (Coining Value.) TOTAL.

TOTAL VALUE OF MINERAL PRODUCTION IN PRINCIPAL COUNTRIES OF THE WORLD, 1898.

AVERAGE TRI-YEARLY VALUE OF THE MINERAL PRODUCTION OF THE UNITED STATES, 1880-1898.

GRAPHIC ILLUSTRATIONS OF THE MINERAL PRODUCTION OF VARIOUS COUNTRIES OF THE WORLD.

Compiled from official sources by Edward W. Parker, Statistician U. S. Geological Survey.

A most striking feature of the chart is the prominent place of the United States in the production of copper, of which metal we produce nearly three times as much as all others combined.

In the production of lead we lead all others, but have quite close seconds in Spain and Germany which will probably continue to be large producers for years to come. Our lead resources, are, however, of great magnitude and the amount of output will probably be limited only by the demand. With the many lead mines already found the output can be very quickly and materially increased should there be the demand for it.

In the production of gold, where we held preeminence for a

number of years, we have to bow the knee to both Africa and Australasia. It is a striking fact that these three greatest producers are all English speaking countries so that the honor of producing nearly all of the world's wealth is kept within the family, for the amount produced by all other countries is very small compared with that produced in Africa, South Africa, Australia, Canada, and the United States.

A consideration of the accompanying tables is not only a source of national pride and satisfaction, but it is a great encouragement in showing that our business is based upon a very solid foundation.

SOLUTION OF TRUST PROBLEMS.

THE Iron Trade Review for September 13, 1900, contained the following very sound reasoning upon the subject of trusts.

"That the trust question is settling itself out of politics, as some of the best students of the problem have insisted it would, appears both from the falling off in the trust-making industry and the rapid declines in trust stocks. In August, as the returns show, New Jersey, West Virginia and Delaware, which lead in the incorporation of trusts, had only a \$68,000,000 total for the capitalization of new companies, \$23,000,000 for New Jersey, \$43,000,000 for West Virginia and \$2,000,000 for Delaware. These amounts include a considerable capitalization of companies other than consolidations. The contrast is very sharp between August and the first two months of last year, for example. In January and February, 1899, the consolidation charters in New Jersey alone showed an aggregate of \$1,048,800,000 in stocks and \$57,500,000 in bonds. This was in comparison with \$916,176,000 of trust capitalization in the same State for the entire year 1898. It is very evident that the craze has subsided into very tame proportions since the early months of July.

Taking another phase of the anti-trust agitation, and the alarmist predictions are also being greatly modified by events. If we may judge from the iron trade, the fear that competition will be destroyed is quite baseless. The independent production of tin plate, wire products, hoops, and bar iron is greater today than at any time since the companies devoted to those special lines were organized, and in each of them more mills are building and will be in operation in the coming year. Prices of these products, which were high last year, not because of the combines, but because everything in iron and steel was in demand beyond the ability of producers to respond, are now low enough to suit the most rabid hater of trusts. Certainly there is no brilliant showing under today's market, for dividends on common stocks, which stand for much of the water that has most disturbed the foes of the combines. That "water" seeks its level, whether in hydraulic systems or in trust stocks, has been plainly demonstrated by the course of the stock market in the past 12 months. For nine well known iron and steel issues the figures are instructive. American Steel & Wire, American Steel Hoop, American Tin Plate, American Car & Foundry, National Steel, Federal Steel, Pressed Steel Car, Republic Iron & Steel and Tennessee Coal Iron & Railroad Co., whose combined issues represent \$480,654,200 showed a decline in market values between Aug. 26, 1899, and Aug. 27, 1900, of \$93,600,037. In most of the stocks named the decline on the preferred and common issues combined ranged from 30 to 45 points. At the prices quoted late in August or at any time in the last two weeks, those who complain of the enormous profits of the consolidations should find opportunities for uncommonly profitable investment. This opportunity, moreover, is open to all comers, and if the critics of the trusts on the score of unwarranted profits have the courage of their convictions they will not neglect the opportunities that are now freely offered in Wall street. As for the underwriters of many of the combines, they will no doubt even now part with much of their holdings at a liberal discount from the ground-floor price. Shrinkages all the way from 10 to 64 points from the original underwriting basis have taken place in well known consolidation stocks.

Up to date the chief sufferers from the combines are those who had most confidence in their securities. The public is being guarded by the operation of natural laws as certain as the processes of the sun.

A. de Kappen has collated the following accident statistics of various foreign countries, which show that in coal-mining the average of fatal accidents per 1,000 miners was as follows:

	1886-1890.	1891-1895.
Germany	2.566	2.450
Russia	2.44	2.522
France	2.105	1.665
Great Britain	1.835	1.526
Belgium	1.754	1.665
Austria	1.548	2.389

COAL TRADE OF THE UNITED STATES. THE WORLD'S COAL SUPPLY AND TRADE. BULLETIN OF THE TREASURY DEPARTMENT, BUREAU OF STATISTICS, Washington, D. C. 110 pages. A very interesting statistical account of the development and growth of coal trade in the United States.

ANNUAL REPORT OF THE SECRETARY OF INTERNAL AFFAIRS OF THE COMMONWEALTH OF PENNSYLVANIA by James W. Latta, Secretary of Internal Affairs; James M. Clark, Chief of the Bureau, Harrisburg, Pa. 580 pages illustrated. In addition to the usual statistics this Report contains a very well illustrated account of the cotton goods industry.

PRACTICAL NOTES ON HYDRAULIC MINING by George H. Evans M. E. second edition published by John Taylor & Co., San Francisco, Cal. 48 pages, price \$1.00. The first edition of this book appeared some three years ago and so successful was it that a second edition has been required. Mr. Evans has put into this small volume a large amount of interesting and valuable hydraulic data drawn from his wide experience in this particular field of mining.

BULLETIN OF THE UNIVERSITY OF KANSAS, Vol. 1, Part 3. Pamphlet, 165 pages with a number of excellent plates. Published by the University of Kansas, Lawrence, Kansas. The typography of the book is most excellent. Its contents include the following: Coccidae of Kansas; The Stratigraphy and Invertebrate Faunas of the Jurassic Formation in the Freeze-Out Hills of Wyoming; the Spermatogonial Division in Brachystola Magna; Annotated List of the Minerals Occurring in the Joplin Lead and Zinc District.

MINERAL RESOURCES OF KANSAS FOR 1899, by Erasmus Haworth, Department of Physical Geology and Mineralogy, University of Kansas, Lawrence, Kansas. 67 pages. This bulletin though short is excellently gotten out and shows the same careful work that has been done by Prof. Haworth in previous volumes. The scope of the book is shown by the following chapter headings: Gold and Silver; Lead and Zinc; Coal; Oil and Gas; Gypsum and Gypsum Cement; Plaster; Building and Other Stone; Clay Products; Hydraulic Cement; Salt.

TRANSACTIONS OF THE AUSTRALIAN INSTITUTE OF MINING ENGINEERS, Vol. VI, edited by A. S. Kenyon, Secretary, Melbourne, Australia. 247 pages. The papers contained in this report are the following: Safety Appliances and Precautions Necessary in Mines, by J. R. Godfrey; Contacts, by W. H. Ferguson; Some Notes on Dry Crushing, by N. F. White; Contouring on Mining Properties with the Aid of the Tacheometer, by H. P. Seale; Diamond Mines and Alluvial Deposits, by P. R. Day; The Manufacture of Sulphuric Acid and Its Use in Metallurgy, by W. H. Mawdsley; Mine Stores, by F. Danvers Powers; The Use of Electricity in Mining, by E. F. J. Holcombe Hewlett.

BULLETINS OF THE UNITED STATES GEOLOGICAL SURVEY, Washington, D. C. The Production of Mineral Paints and Barytes in 1899, by E. W. Parker, 24 pages; Production of Soapstone in 1899, by E. W. Parker, 8 pages; Production of Asbestos and Graphite in 1899, by E. W. Parker, 12 pages; Production of Mineral Waters in 1899, by A. C. Peale, 30 pages; Production

of Abrasive Materials in 1899, by E. W. Parker, 21 pages; Production of Manganese Ores in 1899, by John Birkinbine, 38 pages; Production of Gypsum in 1899, by E. W. Parker, 12 pages; The American and Foreign Iron Trades in 1899, by James M. Swank; Production of Coal in 1899, by E. W. Parker, 203 pages.

MISSOURI GEOLOGICAL SURVEY, Vol. 13, preliminary report John A. Gallaher, State Geologist, Office of the Missouri Geological Survey, Jefferson City, Mo. 259 pages. This volume is divided into two parts. Part 1 is made up of the following chapters: The Synthetic Method of Nature; The Primordial Shell of the Earth; The Geological Record. Part 2 is composed of the following: The Primordial Base; The Geological Record; Cambrian Division; Ordovician Division; Silurian Division; Devonian Division; Subcarboniferous; Lower Coal Measures; Middle Coal Measures; Upper Coal Measures; Forest City Lens; Tertiary, Glacial Drift, River Loess, Soils, and Forestry; Chemical Analysis.

ELEMENTS OF MINERALOGY, CRYSTALLOGRAPHY AND BLOWPIPE ANALYSIS, by Alfred J. Moses, Ph. D., and Charles Lathrop Parsons, B. S., published by D. Van Nostrand Co., New York City, 409 pages, price \$2.00. Part 1 on Crystallography has been entirely rewritten and made to conform to the present special classification. Over 100 additional figures have been added to the text. Part 2 on Blowpipe Analysis has been revised and additional sections upon the use of the spectroscopic and of metallic sodium added. Part 3 contains an introduction to the later study of thin sections of minerals with the microscope. Part 4 on Determinative Mineralogy has been considerably simplified.

IOWA GEOLOGICAL SURVEY, Vol. 10, Annual Report for 1899. Samuel Calvin, A. M., Ph. D., State Geologist. Published by the Iowa Geological Survey, Des Moines, Iowa. 666 pages. The scope of this report is shown by the following table of contents: Administrative Reports; Statistics of Mineral Production; Fossil Fauna of the Kinderhook Beds of Burlington; Geology of Lyon and Sioux Counties; Geology of Osceola and Dickinson Counties; Geology of Hardin County; Geology of Worth County; Geology of Dubuque County. The value of the mineral production in the State during the year is as follows: Coal, \$6,137,576; Clay (estimated), \$2,500,000; Stone, \$809,924; Gypsum (estimated), \$600,000; Lead and Zinc, \$50,542; Iron Ore, \$3,465; total \$10,101,507.

VICTORIA JUBILEE BRIDGE. We have received with the compliments of the Grand Trunk Railway System a splendid souvenir of the Victoria Jubilee Bridge across the St. Lawrence River, which was opened for traffic December 13th, 1898. The volume is beautifully printed on plate paper, illustrated by excellent photographs, and is a complete description of the new bridge and the ceremonies attending its opening; of the old method of reaching Montreal by ferry from Longueuil in 1855; of the old tubular bridge built in 1860, which was replaced by the new one, etc., etc. The volume is a work of art in every respect, and is beautifully bound in an engraved aluminum cover. The Victoria Jubilee Bridge now in use in crossing the St. Lawrence River is one of the best pieces of modern engineering work in America, and its construction by the Grand Trunk Railway System will prove an important factor in the future development and industrial growth of the beautiful City of Montreal and the Province of Quebec.

JOURNAL OF THE CANADIAN MINING INSTITUTE FOR 1900, edited by the Secretary, Mr. B. T. A. Bell, Ottawa, Can. The papers contained in this report are the following many of which have already appeared in the several technical papers. Notes on the Ymir Mine and Its Mill Practice, by Mr. S. S. Fowler; The Small Economies in Mining, by Howard West; The Bridge River Gold Mining Camp, by Fritz Cirkel; The Chicago Main Drainage Channel, by Mr. James F. Lewis; A Method of Cost Accounting with Special Reference to Mines, by Mr. John E. Hardman; Natural Gas in Ontario, by Mr. Eugene Coste; A Prospecting Trip in Northern Omenica, B. C., by Mr. E. C. Gwillim; The Factors in Concentration; The Ontario Mining Law, by Mr. J. M. Clark; The Iron Industry in 1899, by Mr. George E. Drummond; The Old Valley Gravels of the Klondike, Mr. R. G. McConnell; Results in the Use of a Rotary Pump as Against Straight Line Type, Mr. W. Charles Fergie; Notes on Increased Facilities at Wabana Iron Mine, by Mr. R. E. Chambers; Recent Advances in Electro-Chemistry and Electro-Metallurgy, by Dr. W. L. Goodwin; West Kootenay Notes, by R. W. Brock; Mining Pumps, by C. E. Morgan; Are There Diamonds in Ontario? by Mr. A. Blue. One of the most interesting papers is that by Mr. John E. Hardman entitled Method of Cost Accounting with Special Reference to Mines.

A PRACTICAL COURSE IN THE FIRE ASSAYING FOR GOLD, SILVER, AND LEAD OF ORES, BULLION, AND METALLURGICAL PRODUCTS, by Ernest H. Simonds. 92 pages. A separate-leaf note book for students' use in the laboratory and furnace room. Under the head of "General Directions and Suggestions," the author enumerates the principal errors which may enter the results in fire assaying, giving their causes and effects, and showing how such errors may be minimized, and in some cases entirely elimi-

inated by careful systematic work. In "Assignment" 1 the theory, construction, and use of the balance are explained in detail, and examples given for practice in accurate weighing. Assignment 2 treats of miscellaneous mechanical operations such as making cupels, repairing furnaces, rolling out bullion, etc. The remainder of the book is devoted to instruction in assaying proper. Using two well known works on assaying as textbooks and giving numerous valuable references, the author explains and discusses many of the best methods of fire assaying for gold, silver, and lead.

REPORT OF THE BUREAU OF MINES OF PENNSYLVANIA FOR 1899, Part 5 of the Report of the Pennsylvania Department of Internal Affairs. Jas. E. Roderick, Chief of the Bureau of Mines, Harrisburg, Pa. 958 pages. This volume contains detailed statistics and reports from each of the 8 anthracite districts and the 10 bituminous districts of the State of Pennsylvania. There is nothing new or striking in the method of presentation of these reports excepting that the attempt has been made to secure additional technical statistics. In the anthracite region the number of boilers in use is given, the locomotives and whether they are steam or electric; the number and capacity of pumps; the number of electric dynamos and air compressors. In the bituminous region statistics have been gathered under the same headings and in addition data have been compiled showing the character of the appliances for furnishing ventilation, the character of opening in a mine, whether drift, slope or shaft; the mines at which mining machines are in use; the type of machine used and the character of the haulage. This is an interesting and valuable addition to the reports of previous years and should be undertaken for the anthracite as well as the bituminous regions. Reports for the several districts should be presented in a uniform form and summaries should be compiled showing in a condensed form the statistics thus collected.

The Chief of the Bureau in his introduction speaks very highly of the mine inspection service of the State and he says very truly that it is in general being very carefully and conscientiously carried out. The volume is almost twice as large as the preceding one and it is rapidly growing to be a bulky, unhandy volume to handle. This is largely due to very loose open printing in the tabular portions of the book which might be very greatly condensed with advantage to the reader. A proper index would also greatly add to the usefulness of the volume. The present index in the back of the book is merely a table of contents misplaced as no attempt has been made at an alphabetical arrangement.

It seems to have become a settled custom for these reports to be very much belated and the present one has even surpassed those for several years past by appearing nine months after the close of the year for which the report is given. Wherever the fault lies for this lateness it should surely be corrected, for now that the State has a distinct Bureau of Mines, the mining industry has a right to expect that these reports should be issued in time to be of some practical value, as statistical reports are intended for current information and not as historical reference books.

John M. Desloge.

John M. Desloge was born April, 1849, at Potosi, Washington Co., Mo. He finished his education at the St. Louis High School, taking up the profession of mining. His first operation was in the lead business, as Assistant Superintendent of the Desloge Lead Co.'s Works at Bonne Terre, Mo. Here he remained up to the time of the transfer of the mine and plant in 1886 to the St. Joseph Lead Co. From there he went West and spent a large portion of his time in the examination and development of mining properties at various places. In 1891 he accepted the position of Supt. of the Desloge Consolidated Lead Co., developing the mining property and finally erecting the works and mining plant as now in operation. His death on Sept. 7, 1900, was a great loss to his family and friends and deprives the mining world of one of its brightest members.

In a recent paper on Mechanical Draft read before the New England Cotton Manufacturers' Association Walter B. Snow states that from a comparison of a considerable number of plants it appears that under ordinary conditions; a single forced-draft fan with direct-connected engine and short stack can be installed for less than 20 per cent of the cost of a brick chimney. A single induced-draft fan with direct-connected engine and short stack will cost less than 30 per cent of a chimney; and that a duplex induced-draft apparatus consisting of two fans with direct-connected engines inlet and outlet connections and short stack will cost but little more than 40 per cent of a chimney. The latter arrangement is only employed where as in the case of an electric lighting plant, it is the practice to introduce relay units.

CORRESPONDENCE.

This Department is intended for the use of those who wish to express their views, or ask or answer questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided. All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith. The editor is not responsible for views expressed by correspondents in this Department. Correspondence should be in as simple language, and as free from technical terms and formulas as possible, consistent with clear solution. Questions on subjects not directly connected with mining will not be published.

Gypsum or Plaster of Paris.

Editor Mines and Minerals:

SIR:—Kindly inform me where I can find information upon the consumption of plaster of Paris in the United States, its average selling price, and the method used in its manufacture.

Cleveland, Ohio.

G. F. L.

ANS.—The gypsum statistics for the United States during 1899 are contained in the Report of the United States Geological Survey, Division of Mineral Resources, just issued, under title of "The Production of Gypsum in 1899," by Mr. E. W. Parker. This report shows that during 1899, 327,879 short tons of gypsum were ground into plaster of Paris, producing 248,723 tons of calcined plaster, of which the average value was \$3.49 per ton. The method of preparing plaster of Paris is to grind the crude gypsum to a fine powder and then to calcine it at a high temperature in a suitably constructed kettle until the water contained in the gypsum has been expelled. Probably the best work on this subject of gypsum is Vol. 5 of the University Geological Survey of Kansas Reports. An article upon the subject of gypsum and its manufacture into plaster of Paris will appear in MINES AND MINERALS at an early date.

Prospector.

Editor Mines and Minerals:

SIR:—A friend of mine, some years ago, located a mining claim in southern Colorado, and opened up a body of talc in which were imbedded angular pieces of the country rock, which he described as porphyry, quite angular, and boulders of quartz, quite round. The talc was very tough, and could not be shoveled, picked or blasted, to any advantage. The talc when dry could be pounded fine and panned. The result being a lot of small shot from the size of birdshot to a buckshot, of a color a little lighter than lead, very malleable, and about as soft as lead. No assays were ever made, and samples were lost. Would like very much if you could tell me what the metal was.

Yours truly,

Colo. Springs, Colo.

A. S. HOWELL.

This is a somewhat hard question to answer. Talc is a very indefinite and incorrect term used by miners. It generally means with them any soft, decomposed rock such as is produced by kaolinization of the felspar, especially in granite, porphyries and similar rocks. The term "porphyry" is equally dubious as used by the miners, it may have been a true porphyritic rock or only decomposed granite.

As regards the malleable metal found, if it was not lead it is hard to say what it may have been. We can only suggest molybdenum (?). If it assayed very highly, it might be possibly some of the sulphides of silver (?), or horn silver (?), or wire silver (?), but these are not malleable. This question cannot be answered without seeing the samples.

A. LAKES.

Location of Mineral Claims on Railroad Lands.

Editor Mines and Minerals:

SIR:—Will you please inform me through the columns of your paper what steps should be taken in order to locate a mineral claim on railroad lands?

Temescal, Cal.

"PROSPECTOR."

The location "of mineral claims on railroad lands" differs in no respect from the location of such claims upon the public domain; that is, that lands within the limits of the grants to railroad companies known to contain mineral prior to the issuance of patent to railroad companies are subject to location and entry, as in other cases. If, however, patent to a railroad company has issued for such lands, they are no longer public domain and the general land office has no jurisdiction over the same.

A further answer to the above inquiry has been received as follows:

Editor Mines and Minerals:

SIR:—I have yours of the 24th inst. asking for information regarding steps necessary to be taken to locate mineral claims upon railroad lands in this state.

The Southern Pacific Railroad Co. has patent for a large quantity of land, on some of which oil has been found, and some

of which is supposed to contain oil. These lands have been reserved from sale, but the company issues oil development leases on certain portions of them, generally for 160 acres, in 40-acre tracts, to those who desire to go into that business. It has issued a number of them thus far. The conditions are that during the first year the lessee must sink a well on each of the tracts he has leased, to a depth of 2,000 feet or until oil is found at a less depth in paying quantities (10 barrels per day of 24 hours), and that one well shall be sunk on each tract each year thereafter, until four wells are sunk on the respective tracts. The lease runs for 10 years, with privilege of ten more on same terms. The royalty is one-eighth of the gross proceeds. The lessee as a guarantee of good faith must pay, before lease will be issued, \$250 to insure performance of first year's work, and \$8 additional for R. R. acknowledgements, revenue stamps on lease, and recording same. The \$250 will be given back at the end of the first year if the terms of the lease are complied with, otherwise this amount will be forfeited to the R. R. Co.

The company has also large quantities of agricultural lands, at prices ranging from \$2.50 to about \$10 an acre.

Yours truly,

JEROME MADDEN,

Land Agent Southern Pacific R. R.

The Rock Lake Concentrator.

The Rock Lake Mining Co. Ltd., whose office is in Sault Ste. Marie has a copper property situated in the District of Algoma, Province of Ontario, Dominion of Canada, about 35 miles east of Sault Ste. Marie and 9 miles due north of Bruce Mines station on the Canadian Pacific Railroad. This is a copper property and a concentrator has recently been built which is described by the designer as follows:

"The Rock Lake 200-ton concentrator is situated on a suitable side hill of 21 degrees slope on the shores of Rock Lake. It is adjacent to the vein and handy to the lake for water transportation to railway, thereby shortening very considerably the distance concentrates or matte must be teamed. The crude ore from mine is dumped into storage bins so placed at the head of the mill that the ore will fall by gravity into a 20 in. $\times$ 30 in. Blake crusher. The product from the crusher all passes to a 1 in. mesh revolving screen or trommel, the oversize from this trommel going to a set of 16 in. $\times$ 30 in. belt-driven rolls. These rolls are provided with adjustable ball and socket bearings to prevent cramping and consequent wear to shafts. From these rolls the ore is elevated to the above mentioned trommel so that all ore passing to mill has to go through its preparations.

"From this trommel the ore passes to the line of 4 sizing screens, the preparation of these screens being $\frac{7}{8}$ in., $\frac{3}{4}$ in., $\frac{1}{2}$ in. and $\frac{1}{4}$ in., respectively. The oversize from the $\frac{7}{8}$ in. revolving screen is delivered to a coarse jig of special design having plungers provided with parallel motion. The oversize from the other revolving screens is also delivered to jigs having screens to suit the various sizes of ore, and the last screenings from the finest trommel run to a settling tank to be treated on still finer jigs. The middlings from jigs are crushed in another set of 16" $\times$ 30" rolls and elevated into the string of trommels again for sizing and distribution.

"The tailings from jigs are led to a set of high speed 6 in. $\times$ 48 in. rolls, then elevated to a settling tank and fed over Wilfley tables. All material fed on Wilfleys is first sized in a patented sizer where the pulp is thrown by centrifugal force against a screen of 18 mesh to the inch, the oversize being led back to the high speed rolls. Concentrates from jigs and tables are spouted down the mill and settled in large bins from which they will be delivered to smelter. Adjacent to the mill is an engine and boiler room 38 ft. $\times$ 64 ft., in which are placed a 250 H. P. tandem condensing Corliss engine, and 3 tubular boilers of 80 H. P. each, this power plant being amply large enough to furnish the mill with electric light and also drive the mill at a considerably increased capacity, provision for which has been made in the building. The machinery was furnished by Jenckes Machine Co., Sherbrooke, Quebec, made according to designs furnished by the undersigned.

(GEORGE WILLIAMS,

Engineer of Construction,
Butte, Montana.)

Testing for Gas.

Editor Mines and Minerals:

SIR:—I have read with interest the recent articles upon testing for gas, in the April number of MINES AND MINERALS, (page 429), and in the July number, (page 570), as well as the communications of Mr. Davies in April, (page 417), and that of Mr. Mills in July, (page 551). With your kind leave I beg to differ to some extent with all of these gentlemen, and perhaps also with theory. My experience in this regard has led me to believe that the length of the flame cap alone is not a true indication of the

percentage of gas present in the mine air. I claim there is more in the make up of the cap, and its color, than in the height which it attains in the gaseous mixture, and I will try to prove this further on.

I am fire boss for the Cambria Company of Johnstown. There are three fire bosses, and our opportunities are particularly good for making observations in regard to the testing for gas. The mine in which we are employed has been opened up for a distance of three miles from east to west, and about two or three miles from north to south. It is divided into five separate sections or districts, each district having its own circulation; so that an explosion occurring in one district is not liable to affect the other districts of the mine. There are days when one or more of the districts of the mine are idle, and such occasions afford excellent opportunities for the fire bosses to experiment, either alone or in company with each other. We have devoted many such off days to experimenting upon gases; hence our experience.

Mr. Davies gives us in the April number, page 418, seven caps varying in height from $\frac{3}{4}$ " to $4\frac{3}{4}$ ". He says that the first three are not explosive, that is, the caps from $\frac{3}{4}$ " to $1\frac{1}{4}$ ". I have found that such flames or caps at times indicate a highly explosive mixture. Mr. Davies believes that the caps varying in height from $1\frac{1}{4}$ " to $4\frac{3}{4}$ " are highly explosive. I beg to differ from him here. That my friend may be correct theoretically, or even in certain mixtures of gas, I will admit, but how often do we find this in practice? I will agree with him when he asserts the first three caps are the most dangerous, for I believe the most of our explosions occur under conditions producing these flames.

Again Mr. Mills says (July, page 551), that with the normal flame he can get caps from $\frac{1}{4}$ " up to 2", and can detect smaller percentages of gas, and get better results with this normal flame. I think Mr. Mills makes a slight mistake here. I have used the safety lamp, more or less, since the year 1867, and have practiced with lamps of every shape and form, and tried to explode small quantities of gas; tried to pass flame, etc., but failed. I find the normal flame is not correct in all kinds of mixtures. In the strongest kind of mixture, I have observed that the effect is to lower the flame, if anything. In such a case the only way that I could detect the gas would be by a small flicker of the flame, such as it would make in a good current of air. In other cases the flame would not be affected, while, by using a small flame, I could get a cap fully one inch high.

We use the common Davy lamp here, and have used the following oils: First: Sperm oil, the best we could get; the results with this oil were not good. Second: A mixture of four parts of sperm oil with one part Headlight Water White, 150° test. The results with this mixture of oil were good. Third: Headlight Water White, 150° test, with Davies & Sons patent oil burner. This burner gives the most uniform light, and the best results were obtained in its use. I will give some of the caps as we found them. I examined two headings from which air was shut off by water, using a normal flame. My light spindled out to the top of the lamp. I then lowered the flame and tried again, but could not get a cap; the lamp, however, appeared to be full of a very pale blue mixture, the light burning brilliantly all the time. In this mixture we became dizzy and our eyes were heavy. I claimed it to be CO, others said it was marsh gas (CH_4), wanting oxygen. At another time experimenting, I got a cap about one inch high; I tried to raise it, but found an explosion in the lamp resulted every time, producing a deep purple color, sometimes giving off sparks. When this mixture exploded in the heading it appeared stratified, a lower stratum being a deep purple, while the upper stratum of gas was a light blue. At another time I got a nice pale blue cap about $\frac{1}{4}$ " high; I advanced, it raised; I still advanced, and it continued to raise until it filled the lamp and exploded. The question arises, What have I? I get a cap about one inch high, of a very dark blue or indigo; I try to raise my cap, but it explodes every time. This gas is very quick, so is that giving the purple cap previously mentioned. That these are different gases seems to me evident, and again I ask the question: What are these gases? Again, at another time, I get a cap about $\frac{1}{4}$ " high, of a very pale blue or gray color; I advance in it, it turns blue; I still advance, and get a cap the full height of my lamp; the center is of a purple color while the outside is pale blue. This gas also is highly explosive, and I ask, What is it? Again I get a cap the full height of the lamp, very pale blue, inclined to gray; I open my lamp, and insert it into the mixture, but it will not ignite, but forms a halo around the light. I ask, How is this? This mixture gives a cap $3\frac{1}{4}$ " or 4" in height, and will not burn. Again, I get a cap about $\frac{1}{4}$ " high, and have about 2 feet of this mixture. I insert my lamp into the mixture, and get as pretty a cap as I have ever seen; still it will not ignite. Again, I get a cap the full height of the lamp, of a very pale blue, inclining a little to gray. This mixture burns so feebly you can walk away from it. Again, I get a cap of a very, very pale color; sometimes it is hard to detect this, and the mixture will give caps from $\frac{1}{4}$ " up to the full length of

the lamp; often it refuses to ignite, and when it does it burns very feebly.

The statements just made are none too strong, and seem to prove clearly that the height of the flame cap alone is no true indication of the explosive character of the gaseous mixture. I can prove every day in the week that the $\frac{1}{4}$ " cap will explode, and that with the greatest violence; and I beg to say that we need no other occurrence than a naked light to produce ignition. A cap $\frac{1}{4}$ " high does not always represent 4 per cent. of marsh gas, by any means.

About 18 inches or 2 feet above our coal, there is the best kind of a smooth roof. It is as level as it can be made, and like glass. Against this roof the gas often lies in a thin stratum, so that you cannot get a large cap. If you fan it or brush it down upon your lamp, it explodes; if you cant your lamp over, you obtain the same result; if you move your lamp in any way, or hold it in any position, it will explode.

The statements that I have seen and read in books, follow too much on the theory of pure gas and air, and do not consider enough the mixtures such as are met with in mines, and I regret to say for some reason most fire bosses and others, follow in the same line. I have given you no percentages for the gas, in any of the caps I mentioned, for I have no means of ascertaining such percentage; neither have I given you any fine measurements of the heights of a cap, for the only scale we have here is our eyes, and this is the only scale that I have ever seen.

I hope I have not intruded on your generosity, and will say that the above facts can be proven by other parties that have witnessed them.

Yours truly,

Johnstown, Pa., September 24th, 1900. JOHN RETALLUCK.

We always regard very highly such testimony from daily practice. The opportunities afforded such men are numerous, and the fact that a man will improve such opportunities to practice and verify the results of others, and then to communicate his own results and convictions, for the good of others, shows him to be a thoughtful, painstaking man. An extended experience, covering 25 or 30 years, in the use of the safety lamp, in the detection of gas, is not to be idly set aside. It is possible for any of us to be misled, or to misinterpret results of our own investigation, however carefully our observations may be taken.

Our correspondent gives us some valuable testimony. At the same time he makes some statements which need correction; as for example, where he states that Mr. Davies said that the first three caps given by himself, including the $\frac{1}{4}$ " cap (No. 3), were not explosive. On page 417, of the April issue of MINES AND MINERALS, Mr. Davies remarks as follows: "I would say that the flames marked 1 and 2, I have not found explosive, but the flame marked 3, I believe to be explosive at certain times." This statement of Mr. Davies is in complete accord with the results obtained by Mr. Retalluck, who claims that he can prove the explosive character of the $\frac{1}{4}$ " cap obtained from a small, uniform, standard flame.

Mr. Davies rightly states that he believes all other caps above 3, are explosive caps. Our correspondent differs from this statement also. The fact of the matter is that any of these caps may or may not be explosive, in any particular case; but the statement of Mr. Davies referred to, still remains unapproachable, that the higher caps indicate explosive conditions in the mine atmosphere, and must be guarded against with extreme care and caution. This statement will not be questioned. Conditions can always exist in the character of the workings and the manner in which they are maintained, that will make the shorter caps, at times, explosive; or that will render the longer caps at times in explosive; but these conditions are conditions that are local and incident wholly to the general method of mining and ventilation practiced in any particular mine or district. The essential character of each mine gas must be studied as an element, separately and distinct by itself; as the character of each gas is always the same, as far as it is itself concerned. These are the essential elements, which every fire boss and official in charge of a gaseous mine should thoroughly understand, and upon which he should base his reasoning. There are not numerous, different gases occurring in mine workings; but they are few and simple in their character. It is true varying mixtures of these gases produce results which grade between these elementary results, and manifest numerous variations according to the predominance of one or another of the mine gases. We endeavored in a previous article, April, page 429 to make clear this modifying influence in varying mixtures of mine gases; and much that Mr. Retalluck has said in giving his own experience in testing for gases, will be found to conform with what was said in that article. The presence of fine dust suspended in the air of the mine, especially where the coal is soft and inflammable, will give rise to the production of a considerable quantity of carbonic oxide gas. This gas is also formed in the vicinity of a large area of waste or abandoned workings. The presence of carbonic oxide gas undoubtedly has the effect of

lengthening the flame cap; and renders percentages of marsh gas explosive that would not otherwise be so. Under these conditions one of the higher caps, say, 1½" or 2" cap, may result when the quantity of marsh gas is perhaps not greater than 2 or 3 per cent. The gaseous mixture, however, is highly explosive. The color of the flame will also be altered by the presence of carbonic oxide gas. The flame of pure marsh gas is particularly a non-luminous, pale blue flame. The color of this flame is somewhat deepened, and approaches a purplish or violet tinge when any considerable amount of carbonic oxide gas is present. Thus, the color of the flame furnishes somewhat of an index of the character of the gaseous mixture; and our correspondent is correct in his idea that the color of the flame indicates to a certain extent the character of gas present. The color of the flame will be altered very much not only by the percentage and kind of gas present; but by the character of the burning, and amount of available oxygen. In general the paler the flame, the purer the marsh gas or firedamp mixture; and the deeper the flame, the larger the percentage of impure gases in the firedamp mixture.

The effect of the presence of carbonic acid gas in firedamp mixtures is not only to depress the flame and shorten the cap, but to render in explosive such mixtures which would otherwise be highly explosive. These conditions may be extremely local, however; and at a point not far distant, the same current may be found ignitable and explosive, which refused to ignite at that particular point of the workings. The rapidity of the burning of any body of gas is largely an index of the strength of the air current, or the circulation at that point; the more quiet burning indicating a sluggish and deficient circulation. The amount of air present also varies very greatly the intensity of the color of any flame; the larger the amount of air present, the paler the flame.

All of these influences contribute very materially to alter the absolute color due to any percentage or kind of gas in a firedamp mixture; and render more or less uncertain the exact explosiveness of the gas in question in any particular case, except as viewed in the light of the surroundings at the particular point of the workings where the gas test is made. We should consider each test from the basis of a normal state of the mine workings; as, for example, where ventilation is ample, and but a small amount of dust is present in the mine air, and there is the absence of conditions that would yield a large amount of carbonic acid gas (blackdamp.) Every gas test should be made with these modifying conditions clearly in mind; and under no circumstances should one of the higher caps be regarded as safe or in explosive because it appears to be so at any given point of the workings. It should always be borne in mind that any explosive cap may become explosive from the slightest occurrence or change in the conditions prevalent in mine workings.

In conclusion we cannot agree with our correspondent in the setting aside of the height of the flame cap as being the better index of the explosive character of a gaseous mixture; nor with his suggestions in regard to the color of the flame as being a better index of such explosive character, in a gaseous mixture. All of these evidences have their value and bearing; but the height of the flame cap is certainly a more essential element, and will undoubtedly continue to be regarded as a safe index of the explosive character of firedamp mixtures when safeguarded by a broad judgment and intelligent understanding of the influence of other mine gases when present in firedamp mixtures.

Wire Ropes for Transmission of Power.

A recent correspondent writing in reference to the article "Rope Transmission In Mine Haulage," Page 89, MINES AND MINERALS, September, 1900, after commending the article very highly for its practical value, makes some interesting references to the rules in English practice for determining the minimum diameter of sheave, drum, or pulley which can be used for any size rope without injury to the rope. Our correspondent quotes from no less than three of the largest rope manufacturers in Great Britain, and we regard these quotations of so much interest as setting forth clearly the difference between English and American practice in this respect, that we give them below just as they have come to us.

"I am sending you rules by R. S. Newall (the oldest rope maker in Great Britain) for the minimum sizes of pulleys for ropes of given size and make:

Size of Drums or Pulleys.—To determine the minimum diameter of drums or pulleys around which six strand wire ropes may be worked, the following rules will be found useful.

Ascertain the number of wires which form the outside course of one strand. When the cores of the strands are also of wire these are not to be counted, only the outside wires. For 6 wires, square the circumference of the rope and multiply by 8; for 9 wires square the circumference of the rope and multiply by 5; for 12 wires square the circumference of the rope and multiply by 2; for 15 wires, square the circumference of the rope and multiply

by 1.75; for 18 wires square the circumference of the rope and multiply by 1.50; for 21 wires square the circumference of the rope and multiply by 1.25; for 24 wires square the circumference only. The result in each case gives the necessary or minimum diameter of drum or pulley in inches. Larger diameters than these should be adopted when practicable.

When the rope is worked at a high speed, as in shaft winding, power transmission, etc., these rules do not apply. The following should then be used:

Wire Rope Transmission of Power.—For 6 strand 7 wire ropes, pulleys should be 150 times the diameter of the rope; for 6 strand 9 wire ropes, pulleys should be 115 times the diameter of the rope; for 6 strand 19 wire ropes, pulleys should be 90 times the diameter of the rope.

"The White Cross Co., Ltd., who are large manufacturers of ropes and large colliery owners in England, say:

"There is no rule, so far as we know, by which the bending stress of a certain load over pulleys of a given size can be calculated. The fact is, that in this matter, an ounce of experience is worth a ton of theory."

"Geo. Craddock & Company write:

"There is no rule for the respective sizes of ropes and pulleys. It is purely a matter of experience, and how ropes have worked under similar conditions in other places."

These rules or methods of dealing with an important subject are unsatisfactory to say the least. Rope consumption forms one of the most expensive factors in mine haulage, and to say that there is no specific or general rule for determining the sizes of sheaves to be used with different sizes and makes of ropes, and that this can only be determined by experience, places the consumer very largely in the hands and at the mercy of the manufacturer. It is then the judgment and experience of the latter that must dictate the sizes of drums, pulleys, and sheaves for particular ropes. It is his judgment that will arbitrarily say when the life of a rope has proven too short, that this is the result of the use of too small a sheave, and the consumer must abide by his judgment. The general rule that represents very closely American practice in this regard, is that given upon page 91 of the article referred to above, and may be stated as follows:

For steel wire ropes of 6 strands: (7 wires per strand), minimum diameter of sheave is 80 times the diameter of the rope, (12 wires per strand), minimum diameter of sheave is 60 times the diameter of the rope, (19 wires per strand), minimum diameter of sheave is 50 times the diameter of the rope. In the use of iron ropes these ratios are doubled.

It will be observed that there is a vast difference between these general rules of American practice, and the rules stated above as employed in England. This difference consists not merely in the value of a numerical constant, but exhibits a different law of variation, in the two cases; American practice making the diameter of the sheave a multiple of the diameter of the rope, while the English practice, as quoted above, makes the diameter of the sheave a multiple of the square of the circumference, or the square of the diameter of the rope.

The question of determining the bending stress to which the outer fibres of a rope are subjected when passing over a sheave of a given diameter, has received at the hands of scientists a very beautiful theoretical investigation. Theory has thus demonstrated that the bending stress is in proportion to the ratio existing between the diameter of the outer wire of the rope and the diameter corresponding to the curvature of the rope. The expression for this bending stress has been given as follows:

$$\text{Bending stress} = E \frac{d}{D}$$

Where E = modulus of elasticity (steel 26,000,000 to 32,000,000, iron 25,000,000 to 26,000,000),
 d = diameter of single, outer wire of the rope (inches),
 D = diameter corresponding to the curvature of the rope (inches).

It has been further demonstrated, and this important fact has been taken into consideration by American manufacturers, that the radius of curvature which a rope will assume when bending around a sheave, depends upon three factors. (1) The tension or load upon the rope. (2) The angle of deflection or angle of bending. (3) The rigidity of the rope. Regard for these facts has led to the knowledge of a very important factor or element in rope installation, which rope manufacturers cannot afford to ignore however contemptuously they may speak of a theoretical investigation. It is this same theoretical investigation given the subject by our American manufacturers, that has revealed the fact that for a small angle of deflection in the rope, or for a light load upon the rope the radius of the sheave can be much less than the radius of the curvature assumed by the rope, without injury to the rope.

All machine design and the solution of all mechanical problems are today effected along the lines of theoretical investigation. Valuable as practical judgment is, it still remains a fact that this alone would make bungling work out of many of the most important mechanical problems which arise in machine practice. We do not deny that theoretical considerations assume conditions that are rarely realized in practice in their entirety. It is not claimed that theory can express exactly the values of loads and stresses under all the varying conditions of practice; but that certain specific, exact results and values are obtained that furnish a sure and safe guide invaluable to practice. Any practical man who has had a previous technical training will not attempt to deny the value of the exactness of theoretical investigation, and an attempt upon the part of manufacturers to ignore these principles can only result in disaster to themselves, as such a course leads only to confusion and the dwarfing of the advance of science.

Cost of Mine Haulage.

In reply to an inquiry asking for the cost of electrical mine haulage addressed to the electrical engineer of one of the largest coal companies in Western Pennsylvania, the following reply was received:

"In reply to yours, regarding cost of mine haulage, would say that I am not able to give you costs of the purely electrical part of the haulage, since we do not separate this from the total cost from rooms to tippie. This total cost, I find, depends so much upon local conditions (and which have no connection with the electrical part of the haulage), that we can get no reliable data on the cost of delivering coal from main parting to tippie with electric motors. The cost for a single month at twenty mines using electric haulage, was .063 per ton of run-of-mine coal. The average output per mine was 18,200 tons. In thirty-one mines using rope haulage for the same month, the cost was .0765 per ton; average output, 13,200 tons each. In twenty-one mines using mule haulage, the cost was .0604 per ton; average output, 8,500 tons."

Examinations in Iowa.

A recent letter from Iowa states that an examination of mine foremen and hoisting engineers was held at Boone, beginning October 1st and lasting four days. This is the fifth examination that has been held by the Examining Board for this purpose. Two more examinations are expected to be held this year as follows: At Des Moines beginning November 12th, and at Ottumwa beginning December 17th.

The Board of Examiners, as we have previously announced, consists of Floyd Davis, President, Des Moines; James E. Stout, Secretary, Des Moines; Alex. Dargavell, Centerville; John Owens, Beacon; J. W. Lewis, Hiteam. These gentlemen deserve much credit for the manner in which they have taken up and prosecuted the work of examination of so large a number of mine foremen and hoisting engineers. Between four and five hundred men have been granted certificates. Of these nearly one-half were time certificates as provided by law, for a term of service of four years immediately preceding the date when the law takes effect, January 1st, 1901. Few have failed in the examinations, which have been conducted on a broad, practical basis.

Personals.

The Lookout Mountain Coal & Coke Co., with mines at Durham, Ga., has applied for a charter under the laws of Georgia with Mr. George P. Howard, of Atlanta, President; Alvin J. Howard, Secretary and Treasurer; A. W. Evans, Superintendent and Engineer. The property is adjacent to that of the Durham Coal & Coke Co., described in a recent issue of MINES AND MINERALS and the famous Durham coal will be mined, the first car having been shipped September 13th.

F. H. Daniels, of Worcester, Mass., chief engineer of the American Steel & Wire Co., has been especially honored in the Paris Exposition, receiving a gold medal in recognition of the valuable services he has rendered in bringing to a high standard the art of wire drawing and rod rolling; also for attaining a superior degree of excellence in the manufacture of wire goods from wire, and especially for perfecting the Daniels system of copper rail bonds, now in use all over the world. Mr. Daniels had entire charge of preparing the exhibit of the American Steel & Wire Co., and this company has also been awarded a grand prize for major metallurgy, and also a grand prize for minor metallurgy, receiving besides a gold medal for rail bonds, music wires, and other wire products.

W. A. Cornelius, superintendent of the 10-, 23-, and 30-inch mills of the Carnegie works at Homestead, Pa., resigned recently to become superintendent of the operating departments of the National Tube Co.'s works at McKeesport, Pa. D. S. Kennedy succeeds Mr. Cornelius at Homestead.

PRIZE CONTEST.

Prizes Given for the Best Answers to Questions Relating to Mining.

For the best answer to each of the following questions, the value of \$1 in any of the books in our book catalogue, or six months' subscription to MINES AND MINERALS.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue, or three months' subscription to MINES AND MINERALS.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to MINES AND MINERALS.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition Contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed to us not later than one month after publication of the question.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Ninth—In awarding prizes, other things being equal, a carefully written and arranged answer will be given the preference.

Competition Questions for November.

QUES. 628.—*Efficiency of a Pump.*—Determine the efficiency of a pump that is discharging 1,200 gallons of water per minute, under a vertical head of 250 feet, at an expenditure of 125 horse-power. What should be the diameters of the discharge and suction pipes respectively of this pump?

QUES. 629.—*Relative Diameters of Steam and Water Cylinders in Pumps.*—Determine the relative diameters of the steam and water cylinders of a direct acting pump when the vertical lift is 300 feet, the steam pressure at the bottom being 75 pounds per square inch.

QUES. 630.—*Cause of a Shot's Hanging Fire.*—Explain the conditions which may cause a shot to hang fire, in both fuse and electric blasting. In electric blasting is it possible for a shot to explode after the wires have been disconnected and the battery taken away?

QUES. 631.—*Pumping With Compressed Air.*—A direct acting mine pump located at a distance of 500 yards inbye from the bottom of a shaft 300 yards deep, is operated by compressed air. The air is conducted from the surface down the shaft and to the pump, through a pipe 3 inches in diameter. The diameter of the air cylinder of the pump is 10 inches and the piston speed 100 feet per minute. The pump discharges at the top of the shaft, under a head of 1,000 feet. Assuming that the temperature of the compressed air at the surface is 80° F., its temperature at the pump 60° F., and the gauge pressure at the surface 90 pounds, (a) determine the gauge pressure at the pump when the pump is not running. (b) Determine the gauge pressure at the pump when the latter is in operation. (c) Determine the diameter of the plunger of this pump and its discharge in gallons per minute.

QUES. 632.—*Safety Lamps With Copper Gauze.*—State the advantages and disadvantages arising from the use of copper gauze in safety lamps.

QUES. 633.—*Driving Roadways.*—State the manner in which you would drive a main roadway in a seam of coal 4 feet thick, the height of the roadway to be 5 feet in the clear above the rail. The floor of the seam is an underlay that heaves readily. Above the coal is a draw-slate varying from 18 inches to 2 feet in thickness overlaid with a hard slate.

QUES. 634.—*Method of Working an Inclined Seam of Coal.*—Describe in detail the manner in which you would open a breast in a seam of coal pitching 10°. The strike of the seam is N 60° W or S 60° E. The gangways or levels are driven so as to provide drainage toward the shaft. The face cleats of the coal are free and the coal is best worked "longhorn." Give the width of room and room pillars, and the direction in which the rooms should be driven. The general thickness of cover is 250 feet, the coal is a good quality. The roof slate is 18 feet in thickness, and strong, the floor is a hard fireclay.

QUES. 635.—*Bending Stress in a Wire Rope Passing Over a Sheave.*—Calculate the bending stress (lbs. per sq. in.) in the outer fibers of

a 1½" steel wire rope having 6 strands of 7 wires each, when passing over a sheave 9 feet in diameter. If the actual net load upon this rope is 5 tons, what is the factor of safety in the rope?

Answers to Questions Which Appeared in the September and Previous Numbers and for Which Prizes Have Been Awarded.

QUES. 602.—Percentage of Gas in a Ventilating Current.—The ventilating current in a certain district of a mine is charged with gas to the amount of 3 per cent., as shown by the Shaw gas-testing machine. The ventilating pressure in this mine gives a water gauge of 2½ inches. A fall upon the main intake has so reduced the volume of the air current that the water gauge reads only 1 inch. Determine the percentage of gas in this current.

Ans.—Assuming the volume of the return current to be 10,000 cubic feet; then, three per cent. of this quantity being gas, $10,000 \times .03 = 300$ cubic feet is the quantity of gas given off each minute, and the quantity of pure air which enters the district each minute equals $10,000 - 300 = 9,700$ cubic feet. Now this volume of air will vary as the square root of the pressure varies; hence

$$\sqrt{2.25} : \sqrt{1} :: 9,700 : x; \text{ and } x = \sqrt{\frac{1}{2.25}} \times 9,700 = 6,466 + \text{cu. ft.}$$

That is to say with one inch of water gauge, we will have 6,466 + cubic feet of air in circulation. The transpiration of gas increases as the [absolute] pressure decreases; but [the change in absolute pressure being small] the volume of gas, in this case, will not be appreciably affected, and the percentage of gas now in the current equals $\frac{300 \times 100}{6,466 + 300} = 4.44$ per cent., nearly.

JAMES RADFORD, Springfield, Ill.
Second Prize.—D. P. BROWN, Coalbrook, Penna.

QUES. 603.—Ventilation of Dip and Rise Workings.—An inclined seam is worked both to the rise and dip from the bottom of the shaft. The inclination of the seam is 35°. The length of the main incline to the rise is 400 yards, while the dip has a length of 300 yards. The average temperature of the intake airway to the rise is 45° and to the dip 50°; while the temperatures of the return currents, after traversing the gangways of the rise and dip workings are 60° F. and 70° F., respectively. The ventilation in this mine is produced by a fan which is circulating a current of 80,000 cubic feet per minute; 50,000 cubic feet going to the rise workings and 30,000 to the dip workings. The water gauge at the foot of the shaft is 1.5 inches. Owing to an accident the speed of the fan has been reduced and the water gauge has fallen to .5 inch. Determine the quantity of air that will be in circulation under these conditions in both the rise and dip workings.

Ans.—The vertical height of rise incline is $400 \times 3 \times \sin 35^\circ = 400 \times 3 \times .57358 = 688$ ft.; and the vertical depth of dip incline is $300 \times 3 \times .57358 = 516$ ft. The motive column in main intake [water being 816 times as heavy as air] is $\frac{816 \times 1.5}{12} = 102$ ft. The [natural] motive column in the rise incline is $\frac{688 \times 60 - 45}{459 + 45} = 20.48$ ft., and the [natural] motive column in

the dip incline is $516 \times \frac{70 - 50}{459 + 50} = 20.28$ ft. As this motive column in the rise workings acts to retard the ventilation, the effective motive column in the rise incline is $102 - 20.48 = 81.52$ ft.; and likewise as the motive column in the dip workings assists the ventilation, the effective motive column in the dip incline is $102 + 20.28 = 122.28$ ft.

When the water gauge reading at the foot of the shaft falls from 1.5 inches to .5 inch the main intake air column is decreased from 102 feet to $\frac{816 \times .5}{12} = 34$ ft.; the effective air column in

the rise workings is then decreased to $34 - 20.48 = 13.52$ ft.; and the effective air column in the dip workings is $34 + 20.28 = 54.28$ ft. Now since the quantity of air in circulation in any airway varies as the square root of the pressure or air column, we have for the quantity of air passing in the rise workings after the decrease in the water-gauge occurred, $\sqrt{81.52} : \sqrt{13.52}$

$$:: 50,000 : x; \text{ and } x = \sqrt{\frac{13.52}{81.52}} \times 50,000 = 20,362 \text{ cu. ft. In the}$$

dip workings, we have, $\sqrt{\frac{54.28}{122.28}} \times 30,000 = 19,988 \text{ cu. ft.}$
M. FAGAN, Pana, Ills.

Second Prize.—ADOLPHE COOK, Cokeville, Pa.

[The above solution is approximate, since it compares motive columns or air columns of different temperatures, and therefore different densities. It will be observed that the motive columns, as obtained above, are referred to the temperature of the return air, in each case; the formula used being

$$M = D \times \frac{T - t}{459 + t}$$

(see P. C. Ques. 546, page 316, MINES AND MINERALS, February, 1900). To obtain the motive column for the main intake it is assumed that water is 816 times as heavy as air. This is true only when the temperature of the air is 60° F. (bar. 30"). This is a general, approximate method of converting water gauge into air column. The motive columns for the main intake air, thus obtained are, before the accident occurred 102 feet, after the accident 34 feet. These air columns are each for air having a temperature of 60° (bar. 30"). The air column due to the rise (20.48 ft.) has a temperature of 60° F., while the air column due to the dip (20.28 ft.) has a temperature of 70° F. It is not strictly accurate to add and subtract these air columns and the air column obtained for the main intake, except in the first case, for the rise workings, since they are not of the same density.

The solution presented by Mr. Cook was based upon the water-gauge reading; while Mr. John Fyfe, Windber, Pa., and others gave solutions based upon the pressure per square foot. All of these solutions would have had precedence over the solution of Mr. Fagan given above, had they not contained numerical errors, which caused the latter approximate solution to give the closest results. We give below the outline of Mr. Cook's solution, corrected. The method of solution by means of motive columns although a very general method, is one that is often used in such calculations; hence, it would not be considered wrong. At the same time it is liable often times to give results which vary considerably from the truth. There are many of these general methods of calculation in use in mine practice, but they should be avoided wherever it is possible.—EDITOR.]

Rise Workings.—

$$\begin{aligned} 400 \times 3 \times .57358 &= 688 + \text{ft., vertical rise.} \\ 60 - 45 &\times 688 = 19.88 \text{ ft., air column (temp. } 45^\circ \text{ F.)} \\ 459 + 60 &\times 19.88 \\ 1.3253 \times 30 &= .302 \text{ in., water gauge due to rise.} \\ 459 + 45 &\times 5.2 \\ \sqrt{\frac{.5 - .302}{1.5 - .302}} \times 50,000 &= 20,327 \text{ cu. ft.} \end{aligned}$$

Dip Workings.—

$$\begin{aligned} 300 \times 3 \times .57358 &= 516 + \text{ft. vertical fall.} \\ 70 - 50 &\times 516 = 19.51 \text{ ft. air column (temp. } 50^\circ \text{ F.)} \\ 459 + 70 &\times 19.51 \\ 1.3253 \times 30 &= .293 \text{ in., water gauge due to dip.} \\ 459 + 50 &\times 5.2 \\ \sqrt{\frac{.5 + .293}{1.5 + .293}} \times 30,000 &= 19,951 \text{ cu. ft.} \end{aligned}$$

QUES. 612.—Haulage, Load Upon Guide Sheaves.—Calculate the load upon the journals of each guide sheave around a curve in a haulage road. The radius of the curve at the center line of track is 48 feet, and the sheaves are set 26 inches from track center, and 4 feet apart, center to center. The tension upon the rope is 6 tons.

CHAS. E. BOWRON, Birmingham, Ala.

Second Prize.—THEODORE SIMONS, Roseland, B. C.

[Award was made as given above on Ques. 612, but owing to a delay in getting out we are obliged to hold the answer till the December number.—EDITOR.]

QUES. 613.—Timbering, Size of Collar.—In the timbering of the airways of a certain mine, if we use round timber and the depth or diameter of the collars is 8 inches in an airway 8 feet wide, what should be the depth of the collars when the width of the airway is 14 feet?

Ans.—The load round timber will support varies as the cube of the diameter of the timber, and inversely as the length between the supports. The distance between the supports of a collar beam is rarely equal to the width of the entry; but in solving this problem we will assume such to be the case. Denoting the diameter and length of the 8-foot collar by d_1 and l_1 , respectively; and of the 14-foot collar by d_2 and l_2 , we have [since the entire load (wl) supported by the beam varies, for round timber, as the cube of the diameter (d), and inversely as the length (l); or wl varies as $\frac{d^3}{l}$,

and w varies as $\frac{d^3}{l}$; and since the unit weight (w), or the weight on a unit of length of the collar is the same for each collar $\frac{d_1^3}{l_1^2} = \frac{d_2^3}{l_2^2}$; or] $d_2 = d_1 \sqrt[3]{\left(\frac{l_2}{l_1}\right)^2}$. Substituting the given values in this formula we have for the diameter of the 14-foot collar $d_2 = 8 \sqrt[3]{\left(\frac{14}{8}\right)^2} = 11.6$ in.

Or we may reason as follows and obtain the same answer: If an 8-foot collar will support a load of 1 ton, a 14-foot collar of the same diameter will support $\frac{8}{14}$ ton; but under the conditions the

longer collar is required to support $\frac{14}{8}$ ton, [to do which its diameter must be $\frac{14}{8} \div \frac{8}{14} = \left(\frac{14}{8}\right)^2$]. But, since the load a collar will support varies as the cube of the diameter, the diameter of a collar to support a given load varies as the cube root of the load. Hence, in this case, $\sqrt[3]{1} : \sqrt[3]{\left(\frac{14}{8}\right)^2} :: 8 : x$, and the diameter of the 14-foot collar will be $8\sqrt[3]{\left(\frac{14}{8}\right)^2} = 11.6$ in.

JAMES RADFORD, Springfield, Ills.

Second Prize.—J. EDWARD MILLIS, Belle Vernon, Penna.

QUES. 614.—*Timbering, Relation of Diameter to Length of Post.* How should the diameter of prop timber vary with respect to the length of the prop or thickness of the seam? In timbering a certain mine, if 5-foot props are used in the rooms, and these props have a minimum diameter of 6 inches, what should be the minimum diameter for posts set upon the roads in this mine, when the roadway props have a length of 8 feet?

Ans.—The diameter of prop timber (posts) varies [approximately] as the cube root of the length of the post. Hence when using 5-foot room timber, having a minimum diameter of 6 inches, the diameter of 8-foot road props should not be less than $6\sqrt[3]{\frac{8}{5}} =$ say 7 in.

WM. PILKINGTON, Osceola Mills, Penna.

Second Prize.—D. P. BROWN, Coalbrook, Penna.

[We fear from a large number of replies to this question, the rule, in common use, relating to beams (collars) has been interpreted as applying also to post timber. In the latter case there is no law that expresses exactly the relation between the diameter and length of a post supporting a load of compression. Approximately, the diameter varies as the cube root of the length of the post for the same total load on the post, as stated above.—EDITOR.]

QUES. 615.—*Hoisting, Size of Engine.*—Calculate the size of a duplex second-motion engine geared 1 to 3, the ratio of length of stroke to diameter of cylinder being 1.25, that will hoist a maximum output of 1,000 tons per day, from a double compartment shaft 800 feet deep. The weight of the cages is 2,200 pounds each and the weight and capacity of mine cars is 1,400 pounds and 2,000 pounds, respectively. The length of a working day is 8 hours. Allow $\frac{1}{6}$ of the total moving load for friction, and estimate upon the engine as having an efficiency of 60%; the engine to cut off at $\frac{3}{4}$ stroke, the boiler pressure being 90 pounds per square inch. No balance rope is used beneath the cages.

Ans.—On account of the depth of this shaft (800 ft.) and the comparatively light cars (capacity 2,000 lb.) indicating a seam not exceeding 4 or 5 feet in thickness we will assume two cars are hoisted at a time.

The number of hoists per hour will be $\frac{1,000 \times 2,000}{2 \times 2,000 \times 8} = 62.5$ hoists. Allowing 30 seconds for caging cars, the actual time of each hoist will be $\frac{(60 \times 60) - (62.5 \times 30)}{62.5} = 27.6$ sec., and the speed of winding will be $\frac{800}{27.6} =$ say 29 ft. per sec., or 1,740 ft. per min.

Assuming a $1\frac{1}{2}$ inch plough-steel rope, weighing 2 pounds per lineal foot, the ascending load on the rope will be $2 \times 800 + 2,200 + 2(1,400 + 2,000) = 10,600$ lb. = 5.3 tons. The breaking load of a $1\frac{1}{2}$ inch plough-steel rope is 60 tons, which gives a factor of safety for this load after doubling the actual load to provide for shocks, $\frac{60}{2 \times 5.3} = 5.66$, thus giving ample security.

The total moving load is $10,600 + 2,200 + 2 \times 1,400 = 15,600$ lb., and the friction of the system will be $\frac{1}{6} \times 15,600 = 1,560$ lb. The unbalanced load is $10,600 - 1,560 = 9,040$ lb., and the load on the engine will be $9,040 + 1,560 = 10,600$ lb. The required effective horsepower of each cylinder is therefore $\frac{10,600 \times 1,740}{33,000} =$ say, 378 h. p. The efficiency of the engine being 60%, the total horsepower required of each cylinder, for this hoist will be $\frac{378}{.60} = 630$ h. p.

The gauge or boiler pressure being 90 pounds, and steam being cut off at $\frac{3}{4}$ of the stroke, the mean effective pressure in the cylinder is found by the formula M. E. P. = $.9[c(p + 14.7) - 17]$, in which p is the boiler or gauge pressure, and c a constant. (See table, page 379, MINES AND MINERALS, March, 1900). Substituting values, M. E. P. = $.9[.917(90 + 14.7) - 17] = 71.11$ lb.

Assuming that the engine makes 400 strokes per minute, the number of revolutions of the drum, in the same time, will be

$\frac{400}{3 \times 2} = 66\frac{2}{3}$, and the diameter of the drum will be $\frac{1,740 \times 3}{200 \times 3.1416} = 8.3$, say 8' 4". The diameter of the cylinder will be

$$\sqrt[3]{\frac{630 \times 33,000 \times 12}{7854 \times 71.11 \times 1.25 \times 400}} = 20.75,$$

and the length of the stroke = $20.75 \times 1.25 = 25.94$ in.; size of engine, say 21" $\times$ 26".

Second Prize.—CHAS. E. BOWRON, Birmingham, Ala.

QUES. 616.—*Tail-Rope Haulage.*—The haulage in a certain mine is to be accomplished by the tail-rope system. The distance from the tail sheave to the shaft bottom is 1,500 yards, and the shaft is 350 yards in depth, the engine being located upon the surface at the mouth of the shaft. The seam is generally flat, but there are up and down grades in the haulage road, the steepest being a 10%-grade in favor of the empties. Calculate the size of rope and the effective horsepower required from this haulage, assuming an output of 900 tons in 10 hours, the weight and capacity of the mine cars being 1,200 and 1,800 pounds respectively.

Ans.—We will suppose that the tail rope is carried on the surface to a point above the tail sheave, and thence down a bore hole into the mine; also that the main and tail ropes are of the same size. Assuming a speed of winding of 12 miles per hour, or 1,056 feet per minute, the actual running time of a round trip will be $\frac{1,500 \times 3}{1,056} \times 2 = 8.52$ minutes, and supposing 2 minutes

are required for changing ropes at the shaft bottom and inside parting, each, the total time consumed in making a round trip will be $2 + 2 + 8.52 = 12.52$, say 12.5 minutes. The total number of cars handled per day will be $\frac{900 \times 2,000}{1,800} = 1,000$. The

number of trips per day will be $\frac{10 \times 60}{12.5} = 48$; and the number of cars in each trip will then be $\frac{1,000}{48} = 20.83$, say 21 cars. The

seam being generally flat the greatest pull on the rope will occur when the loaded trip is ascending the 10% grade, since this grade rises towards the shaft; and we calculate for this maximum pull on the haulage rope.

Let T = pull on rope (lb.);
 W = weight of loaded trip (lb.);
 w = weight of rope per lineal foot (lb.);
 l = length of both ropes; equals twice the distance from drum to tail sheave (ft.);
 d = vertical drop of rope in shaft (ft.);
 a = slope angle of maximum grade.

A grade of 10% is equal to a pitch of $5^\circ 43'$. Assuming a $\frac{1}{2}$ -inch plough-steel rope, having 6 strands of 7 wires each, and weighing 1.12 pounds per lineal foot, the gravity pull of the rope will be the pull of that portion of it that hangs vertically in the shaft, since the gravity pulls of the main rope upon the several up and down grades of a flat seam will balance each other. Then, for the tension upon the main rope, at the winding drum, we have,

$T = W\left(\sin a + \frac{\cos a}{40}\right) + w\left(d + \frac{l}{40}\right)$. Substituting given values,
 $T = 21(1,200 + 1,800) \times \left(.0996 + \frac{.995}{40}\right) + 1.12\left(350 \times 3 + \frac{1,500 \times 3 \times 2}{40}\right) =$ say 9,270 lb., or 4,635 tons; giving a factor of

safety of $\frac{33}{4.635} =$ say 7, since the breaking strain of this rope is 33 tons.

The effective horsepower of the winding will be $\frac{9,270 \times 1,056}{33,000} = 296.64$ h. p.

EVAN C. DAVIES, Duryea, Pa.

Second Prize.—CHAS. E. BOWRON, Birmingham, Ala.

[In the above answer, the fact has been overlooked that since the tail rope is conducted over the surface, and descends into the mine through a bore hole at the tail sheave, its weight in descending is subtractive from the friction pull of the tail rope on the rear end of the trip. Since, in this case, this descending weight exceeds the friction pull of the tail rope, the latter should not be considered. This would reduce the tension or load upon the main rope 126 pounds, giving for this load $9,270 - 126 = 9,144$ lb.—EDITOR.]

QUES. 617.—*Safety Valve.*—The distance from the fulcrum to the stem of a safety valve is 5 inches, the diameter of the valve seat $2\frac{1}{2}$ inches, the weight of the lever 15 pounds, and its center of gravity 10 inches from the fulcrum. If the ball weighs 75 pounds, how far should it be set from the fulcrum, in order that the valve will blow off at a boiler pressure of 90 pounds per square inch?

Ans.—Since the valve is 2.5 inches in diameter and the

required boiler pressure 90 pounds per square inch, the total pressure on the valve, at the moment preceding the blowing off, is $.7854 \times 2.5^2 \times 90 = 441.7875$ lb. To balance this upward pressure acting with a leverage of 5 inches, we have a weight of 15 pounds (weight of lever) acting with a leverage of 10 inches, and a weight of 75 pounds (weight of ball) acting with a leverage

of x inches. Since these opposing forces are in equilibrium, their moments are equal, and we have $75x = 441.7875 \times 5 - 15 \times 10$; whence $x = 27.4525$ inches.

[The moment of the force acting to raise the valve, must equal the sum of the moments of all the forces acting to depress the valve; or expressed as a formula (See Fig.) if W and W_1 are the weights of the ball and lever, respectively; and P the total steam pressure on the valve V , the center of gravity of the lever being at G , we have, $Pa = Wd + W_1c$.]

C. D. WRAY, Lillooet, B. C., Can.

Second Prize.—CHAS. E. BOWRON, Birmingham, Ala.

QUES. 618.—*Energy of Fly Wheel*.—The fly wheel of an engine measures 6 feet in diameter, out to out, and 8 inches on the face, the thickness of the rim being 3 inches. If this wheel is set upon the crank shaft of a $12'' \times 16''$ engine, at what speed will the stored energy of the wheel equal the power of the engine, assuming a mean effective cylinder pressure of 50 pounds per square inch?

[This interesting and practical question still remains open, and we hope it will receive the attention it deserves. All of the answers received were wide of the mark.—EDITOR.]

QUES. 619.—*Ventilation, Splitting Air Currents, Power Constant*. The ventilation of a certain mine is accomplished by means of a fan running at a speed of 150 revolutions per minute. The maximum power of the engine is being employed, but the quantity of the air in circulation is not sufficient to meet the requirements. If it were possible, in this mine, to divide the ventilating current into two equal splits, still retaining the same power of the ventilator, would the quantity of air in circulation be doubled by this means? If you say No, please explain why.

ANS.—Assuming the mine in question to be reached through a deep shaft or a long slope, or to have any long main intake airway before arriving at the point where the air is divided, the providing of two equal splits (power remaining the same), while materially increasing the volume of the air, will not double the quantity of the circulation. The reason for this lies in the fact that in order to double the quantity of air circulating in a mine, by dividing it into two equal splits, we must maintain the same effective power in the mine. But an increase of power will be required in the shafts or main airways where the current is not divided; and this we cannot do.

By splitting the current we have changed the conditions in the mine; but the conditions as to depth, size and rubbing surface of the shafts or main airways remain the same as before. The passing of an increased volume of air through the shafts or main airways of a mine can only be accomplished by increasing the power formerly available in such shafts or main airways. Under the conditions of the question, such increase of power can only come from the power effective in the mine, and this fact makes it impossible to double the quantity of air in circulation by the method named. [The same reasoning applies to the passage of the increased quantity of air through the fan. This can only be accomplished by an increase of power, at the expense of the circulation, which is therefore, not doubled by splitting.]

JOHN VERNER, Oskaloosa, Iowa.

Second Prize.—J. EDWARD MILLS, Belle Vernon, Penna.

Ventilating Two Mines As One.

The following was received sometime since in criticism of the answer to Prize Contest, Question No. 522, published in MINES AND MINERALS, page 173, November, 1899.

I will not presume to enter this in the contest since the allotted time has expired. I hope, however, that if there is any error in Mr. Eicher's answer it will be rectified or that I may be enlightened and set right. What could Mr. Eicher mean where he says, "without changing the above named conditions," when it is the change that we were called to contemplate? If in any particular mine having a circulation of 20,000 cubic feet of air, the power be doubled there will undoubtedly result about 25,000 cubic feet, due to this increase of power; but what of that additional mine?

I desire to learn how the answer of Mr. Eicher can be correct,

in the present case. I give below the method I should employ in the solution of the example.

QUES. 522.—Our mine is ventilated by a furnace; the mine adjoining us is ventilated by a fan. The workings are approaching each other very rapidly and it is proposed, when the workings come together, that we shall throw the circulation of the two mines into one. Practically 20,000 cubic feet per minute is the present circulation of each mine, and it is argued that by throwing them together and allowing both furnace and fan to work upon the airways we will have in circulation double this amount of air, or 40,000 cubic feet of air passing. Please give me your opinion in regard to this.

When the workings will be joined, it is proposed to throw the circulation into one (one circulation, not one mine). The furnace, at least, marks the outlet. If the volume varies as the cube root of the power and inversely as the square root of the rubbing surface, and supposing the airways to be equal in area; then, for the power, we have $1 + 1 = 2$ and $\sqrt[3]{2} = 1.25$, and likewise for the rubbing surface of the two mines, $1 + 1 = 2$, and $\sqrt[3]{2} = 1.44$; then, $1.44 : 1.25 :: 20,000 : 17,361$ cu. ft. The loss is due to the increased friction, or high velocity.

W. H. McCLEARY, Pennsville, Pa.

[In Ques. 522 the ventilation of each mine is accomplished in a single split or air current. These separate circulations are to be thrown into one circulation as soon as the mine workings come together. Our correspondent rightly assumes that the power producing the combined circulation will be double the power of either fan or furnace, since the fan and furnace (assumed of equal power) are both working upon the same current. It is wrong, however, to assume, in this case, that the quantity varies inversely as the square root of the rubbing surface. This is only true when the pressure remains constant, which is not the case here.]

There are in reality two cases which we may consider in the solution of this example. (1) When the workings come together the air current may be conducted from the inlet of one mine to the outlet of the other mine, or from the fan to the furnace (which furnishes the upcast) in a single current, and we understand that Mr. Eicher's words "without changing the above named conditions," refer to the conducting of the new current in a single split after the connection is made, as was previously done in each mine. (2) When the connection is made the current may be conducted from the inlet of one mine to the outlet of the other mine in two splits or airways. Mr. Eicher's answer considers the first case where the ventilation, after the connection is made, is accomplished by a single current, the same as before in each separate mine. In this case, the circulation of one mine (20,000 cu. ft.) is the original quantity. After the connection is made the power is double the original power applied to this circulation, the rubbing surface and the area remaining unchanged; that is to say, the rubbing surface of one single airway, from inlet to outlet of the two mines, is practically the same as the rubbing surface of the original airways, intake and return, in one mine, and the area likewise. The formula expressing the work in terms of the quantity and of the mine is, $u = \frac{k s q^2}{a^3}$; whence by transposition we obtain, dropping the constant k and extracting the cube

root, q varies as the expression, $a \sqrt[3]{u}$. Or since a and s remain unchanged and the power is double the original power in this case, q varies as $\sqrt[3]{2}$; or, $q_1 : q_2 :: \sqrt[3]{1} : \sqrt[3]{2}$, or $20,000 : x :: 1 : \sqrt[3]{2}$, and $x = 20,000 \times \sqrt[3]{2} = 25,198 +$ cu. ft.

In the second case where the air is made to travel in two separate splits from the inlet of one mine to the outlet of the other mine, the power, rubbing surface, and area are all doubled, and we have $20,000 : x :: 1 : 2 \sqrt[3]{2}$, and $x = 20,000 \times 2 = 40,000$ cu. ft.

These are the only two cases which we have a right to consider. In every case the quantity of air in circulation will vary as the expression $a \sqrt[3]{u}$. In no case could the answer obtained by our correspondent (17,361 cu. ft.) be correct.

We are glad at any time when a short discussion of one of these answers will throw any new light upon the subject, to have any of our correspondents write us in regard to the same. In this connection, we might mention, however, that a correspondent recently wrote us in regard to the answer to question No. 573, in which the depth of a shaft was calculated from the observed time required for a stone to drop to the bottom of the shaft and the sound to return to the top. The total observed time was 10 seconds, and this correspondent calculates the distance the stone will fall in this total time, which is obviously wrong, since the 10 seconds includes also, the time required for the sound to return to the top of the shaft.

The same correspondent questions also the velocity of sound in dry air at 60° F., given in answer to the question as 1,125 feet per second, and states that this velocity, according to Herschel, is given as 1,089 feet per second at 32° F. The velocity of sound, as determined by the theoretical calculations of Prof. Rankine (Phil. Trans., 1870), is 1,090 feet per second at a temperature of 32° F. The experimental determination of the velocity of sound according to numerous experiments made at different times and in different countries, gives a velocity of 1,091.7 feet per second in one case; 1,090.6 feet per second in another case, and 1,092.8 feet per second in a third case, with a temperature of 32° F. in each case. These figures, both experimental and theoretical, corroborate very closely the figures given in answer to this question. There are numerous influences, principally atmospheric, that alter the velocity of sound. The intensity of the sound also affects its velocity. The moisture of the air in the shaft would have the effect to increase the velocity of the sound. Taking these facts into account we consider the velocity of 1,125 feet per second, at a temperature of 60° F., as very close in this case.

It is further suggested by this correspondent that there is no formula given in the answer, for finding how far a body will actually fall in a given time, and he recommends the use of the formula, $D = t^2 \times 16\frac{1}{2}$. The formula given in the answer is the formula employed to calculate the time of the fall through a distance D , and is $t = \sqrt{\frac{2D}{g}}$. It will be observed that this is the same identical formula transposed, as suggested above, but our correspondent takes the value of $\frac{g}{2}$ as $16\frac{1}{2}$, making $g = 33$, whereas the correct value is $g = 32.16$ for this latitude.

We believe the endeavor we have made to make this Department practical, clear, and concise, is appreciated by the increasingly large number of contestants. In all cases it is the aim to quote only figures from the highest authorities. Although we cannot always give ourselves the pleasure of a reply, we assure contestants that their criticisms are appreciated, and whenever new light is thrown upon a subject by such criticism the same will be published together with our reply in the correspondence columns. We notice a slight typographical error occurred in the answer to Ques. 573, page 507, June 1900. In the next to the last line of this answer the radical sign was omitted from the expression $\frac{2D}{32.16}$.

This should read $\sqrt{\frac{2D}{32.16}}$ as in the fourth line above. This does not affect the answer.—EDITOR.]

TRADE NOTICES.

Babcock & Wilcox boilers have been awarded Grand Prix at the Paris International Exposition.

The Westinghouse Air Brake Co. has just ordered from The Burt Mfg. Co., of Akron, Ohio, a large Cross Oil Filter to equip its power house.

The Sullivan Machinery Co., of Chicago, wish to give notice that they have recently opened a branch office in Spokane, Wash., at 101 S. Howard St. This office is in charge of Mr. M. J. Ready, and the firm will carry there a complete line of rock drills, diamond drills and supplies for same.

The Sullivan Machinery Co., of Chicago, has moved its offices from 54-60 North Clinton St., to the Merchants Loan and Trust Building, 135 Adams Street, Rooms 1220-1221 where the Officers of the Company will be very glad to see their friends. The store and shipping department will remain on Clinton St.

The Jeffrey Mfg. Co., of Columbus, Ohio, announces in its advertisement on another page that its new chain catalogue is now ready for distribution. As this firm has a well established reputation in the line of chains and chain belting it will pay any one interested to write for this catalogue, which will be sent for the asking.

Owing to erroneous information we stated in the last issue of MINES AND MINERALS that the Grand Prize for mining machinery at the Paris Exhibition was awarded The Rand Drill Co. We are informed by them that this was an error and that while the Rand Co. received three gold medals, they did not receive the Grand Prize.

The Rand Drill Co. has removed its main office from 100 Broadway, New York, to the 15th floor of the new building just erected by the American Exchange National Bank, at 128 Broadway, corner of Cedar St., to which place all future correspondence should be addressed. In its new office the company will occupy

the entire floor in conjunction with its allied interests: The Pneumatic Engineering Co., the Rendrock Powder Co., and the Davis Calyx Drill Co.

The Jeffrey Mfg. Co. has recently received notice from the Director of Machinery and Electricity of the United States Commission to the Paris Exposition that the Jeffrey Co. has received a gold medal in class 63; a silver medal in class 23 and a bronze medal in class 21. These classes cover chain belting, elevating and conveying machinery and coal mining machinery.

The Aultman Co., engineers, founders and machinists of Canton, Ohio, has arranged with the C. T. Patterson Co., Ltd., of New Orleans, La., to represent the Company in the sale of its complete line of elevating, conveying and power transmission machinery. A competent engineering force will be at hand to give prompt and intelligent attention to all inquiries received for this class of machinery.

The Pittsburgh Gage & Supply Co., of Pittsburgh, Pa., manufacturers of the Pittsburgh safety water column which is a very simple and effective device and one that is claimed to automatically and unfailingly protect the steam boiler. Notwithstanding the precautions taken in the manufacture of steam boilers to make them safe they are nevertheless liable to accidents which are disastrous to life and property, but when provided with a safety water column this danger is largely obviated. The happy and effective combination of simplicity, durability and accuracy has made the Pittsburgh Safety Water Column a winner in its particular field and the Pittsburgh Gage & Supply Co. is having a highly satisfactory trade in these water columns, requiring its factory to be in operation night and day. The literature of the company is bright, pointed and very handsomely gotten up and well worth the reading.

The Thornton N. Motley Co., 43 John St., New York City, licensees for Eastern United States and foreign countries for the sale of the Jackson Hand Power Rock Drill, report that in the week ending July 14 they received orders from France, Nova Scotia, Mexico and two South American countries. Aside from the above they have made sales in Hawaii and to a number of leading concerns in the United States. Jackson drills are now in use in a large portion of the leading mining camps in the Western United States, in Hawaii and the following foreign countries: Belgium, France, Germany, Russia, New Zealand, Australia, Honduras, Cuba, Colombia, Mexico, Nova Scotia, Canada and Siberia. The above named licensees report that one sale in August was of 15 drills to a West Australia party and orders received in September before the first week had expired amounted to 35 drills for September delivery.

The Cherry Chemical Co., 1215 Filbert St., Philadelphia, Pa., manufacturers of the Red Seal boiler compound, state that their agent in Tien Tsin, China, has returned safely to the United States. While this will temporarily interfere with their business in Asia, they believe in a short time that their export trade will largely increase. They have recently received a letter from China, stating that the compound has given satisfaction far beyond the expectation of the user. This compound is manufactured dry, in the form of a granulated powder, in appearance resembling common brown sugar. It is put up in half barrels, barrels and kegs, weighing from 100 to 1,000 pounds, for the convenience of large and small customers. It readily dissolves in hot water, and can be applied in a dry state through the man hole, or in a liquid state through the feed pump. The makers claim that when this compound is used according to the directions, it will never fail to meet the most sanguine expectation of the purchaser, being composed of chemicals which are harmless to the boiler material. This compound has been endorsed by professional men and many of the very best engineers.

Correction, Answers to Examination Questions.

[In the answer to Ques. 13, page 134 of the October issue, the formula at the top of the second column should read,

$$d = \sqrt[3]{\frac{u}{.7854 prn}} = \sqrt[3]{\frac{12 \times 750 \times 33,000}{.60 \times .7854 \times 71.1 \times 1.4 \times 150}} = 34.8 \text{ in.}$$

And in the second line following, for the length of stroke we have, $34.8 \times 1.4 = 48.7$ inches. The size of engine required for this hoisting is, therefore, say $35'' \times 48''$ instead of $14'' \times 20''$ as stated. This was an error of calling u the work in foot-pounds instead of inch-pounds, and omitting the factor 12 from the above equation. The size of this engine could be much reduced by employing a second motion engine, geared say 1 to 4, or by using a double-deck cage and hoisting two cars at a time.

Attention was called to this omission by Mr. Chas. Power, Manager Issaquah Coal Company, Seattle, Washington, to whom we are indebted for the kindness.]

THE DEEPEST MINE IN IDAHO.

The Ramshorn, at Bayhorse—The Mineral Wealth of the Region. Its Development and Geology.

Written for MINES AND MINERALS, by R. N. Bell.

In the Ramshorn Mine of Bayhorse, Custer County can claim the distinction of having the deepest and best developed copper-silver mine in Idaho.

This famous old property was worked very extensively during the eighties, and produced silver, copper and gold bullion to the value of \$2,500,000.

The principal values being in silver, active production of ore at the mine was discontinued when the white metal commenced to suffer such a rapid decline in value. A small force of men, however, has been kept constantly employed on the property entirely on development work, and the mine has since only shipped two or three carloads of selected ore, each year, sufficient to pay current expenses.

Today, the Ramshorn Mine, has six miles of open workings, exposing measurable bodies of ore, which according to conservative estimates, contain an aggregate gross value of \$3,000,000. Besides which, all the surface ore bins, and most of the chutes and cross cuts in the mine, are stacked full of loose ore, ready for shipment. There is fully 3,000 tons of this loose ore, and its average value in silver and copper is \$100 per ton.

The canyon of Bayhorse Creek in which the Ramshorn Mine, and most of the other big mines of the Bayhorse District, are situated, is deep and narrow, and presents an elaborate cross section of the geology of the region, as it cuts the formations almost at right angles to their trend.

The formations embrace various horizons, from the Carboniferous blue limestone, down to the Archean granite. Associated with them are to be found enormous intrusions of diorite, syenite, quartz porphyry, and other more recent igneous rocks, together with the usual evidence of faulting, folding and fissuring, generally accompanying these formations.

This is a combination of geological and physical conditions, which has come to be recognized the world over as the most reliable manifestation of the presence of great mineral wealth, and in the State of Colorado this combination is regarded as almost essential in the establishment of successful mining camps, and the prolific production of the precious metals.

The exposed granite core of this portion of the Salmon River Range, at the head of Bayhorse Canyon, is overlaid by a thick series of heavy bedded Cambrian quartzite, and above the quartzite, several thousand feet of dark colored metamorphic slates. Overlying the slate again, come a series of Carboniferous blue and grey limestone, and dolomite, nearly 1,000 feet thick, and above the lime the foothill formations for a width of two miles are made up of tertiary lavas, tuffas, and recent sediments.

This same series of formations in the same general order, flanks the southeast slope of the range in a crescent shaped sweep for a distance of 30 miles, and is extensively mineralized the entire distance.

The Ramshorn vein is a compound fissure, cutting across the bedding planes of the thick series of metamorphic slates, almost at right angles. It courses north and south, and dips west, at an angle of 50 degrees.

The pay streaks occur on either wall of a zone of crushed slate. They are about 60 feet apart, along the upper workings, and give the appearance of two closely parallel veins. But as development was extended down, these pay veins gradually approached each other, and in the lower levels of the mine, are not to exceed 20 feet apart. They will probably unite at further depth, and make one strong vein of pay ore. The pay shoots now exposed in the various levels, are from six inches to six feet thick, and carry values of from \$25 to \$500 and \$1,000 per ton. The walls are clean cut, and well defined, and the mineral readily separates from the gangue.

The principal minerals contained in these pay veins, are brown and white carbonate of iron, mixed with chloride of silver and gray copper, with very little quartz. In the upper workings of the mine, the rich sandy brown chloride predominates, but in the lower levels, the copper sulphides are in excess. The writer sampled one shoot of clean gray copper ore, over 24 inches thick, that yielded an average value of 1,200 ounces of silver, and 25 per cent copper, and was informed that these shoots of clean high grade ore, sometimes swelled to four feet wide, and that the average of all the ore mined had been in excess of 100 ounces of silver.

Nature did a good deal for the development of the Ramshorn vein. The narrow canyon of Bayhorse Creek, is equivalent to a vertical shaft, already dug. The vein courses square into the north side of the canyon, and is covered by five contiguous claims,

following its apex for nearly 7,000 feet, and giving a vertical lift of something like 4,000 feet between the point where the vein crosses the creek level and the extreme north end of the property.

The method of development consists of a system of adit tunnel lifts driven in on the vein, at intervals, as it courses down the face of the mountain, and connected underground, with a regular system of raises, chutes and manways, for the ventilation and economical handling of the ore bodies.

At the mouth of the principal tunnel openings, there are substantial ore bins, arranged to feed a Halliday wire-rope tramway, by which they are all connected to the principal storage bin at the foot of the mountain, now filled with 1,000 tons of loose ore having an average value of 100 ounces of silver, and about five per cent copper.

There is sufficient stoping ground now opened on the numerous ore shoots, to accommodate 250 miners breaking ore, without being in each other's way. This ore carries an excess of free smelting iron, and with its other advantages, and railroad transportation added, this property will prove one of the most profitable mines in the state.

The longest tunnel on the Ramshorn, which is driven in on the vein all the way, was started several hundred feet above the creek level. It has penetrated the mountain 3,000 feet, and shows a handsome body of ore in the present face, nearly three feet wide. The steep pitch of the mountain, into which this vein and tunnel course, gives a vertical face depth of 3,000 feet. This tunnel together with its miles of connections probably constitutes the deepest development of any ore vein in the State of Idaho, and amply refutes the argument that Idaho mines do not go down.

Nearly parallel to, and adjoining the Ramshorn Mine, the old Skylark Group, carrying the same character of ore in the same formation, has been a famous producer. This mine has been worked continuously, for the past 20 years. It is also developed by a succession of adit tunnel lifts with systematic underground connections aggregating something like 18,000 feet in length. It has produced gold, silver and copper bullion to the value of \$2,500,000, and shipped \$25,000 worth of ore last year. The Skylark vein was more irregular and disturbed in its upper workings than the Ramshorn, but in its lower levels it shows a more regular tendency and steeper pitch, and the indications are that its greatest resources of mineral wealth still await systematic development in depth, which can be continued by successive adit tunnel lifts for fully 3,000 feet farther down the side of the mountain before the apex of the vein would strike the Creek bed, on its present course.

The longest tunnel on the Skylark is 2,400 feet, which carries the regular fissure wall of the vein throughout its entire length. This tunnel is still being pushed ahead, and a shoot of rich ore has been developed on its course within the past month.

Besides these two great properties, there are numerous other mines and prospects on the slate belt, extending for miles in a north and south direction, most all of which are idle at the present time, owing to the low price of silver, and the lack of transportation facilities. The most notable of these are a group of mines on Poverty Flat Mountain, which have been worked at a comparatively shallow depth, but have a bullion record of \$1,500,000.

Some of the fissures in the slate belt are very irregular in their upper horizons, but persistently continuous, and I believe will go down to an indefinite depth, and probably carry much more regular values when the underlying igneous rocks that produced them have been reached. This intrusion of igneous matter, which is partially manifested by a laccolitic crown in the bottom of the canyon below the Ramshorn and Skylark mines, must have been of phenomenal proportions, as there is unquestionable evidence that it has thrown out intrusive sheets miles in extent, underlying the whole southeast slope of the range.

These conditions offer the most inviting field for deep mining, especially in the lead belt, where the results already obtained, I believe, are only a trifling surface manifestation of what lies below.

This great intrusion of igneous rock is responsible for the gradual folding and faulting of the sedimentary formations into the parallel line of mountain uplifts, constituting Ramshorn, Keystone, Poverty Flat, and Bald Mountains, which reach elevations 9,000 to 10,500 feet above sea level, and one to three thousand feet above the main granite divide, or water shed of the district, separating the waters of Yankee Fork from the Salmon River.

Three miles below the Ramshorn Mine, around the town of Bayhorse, are situated some very fine lead-silver properties, among which the principal producers have been the Beardsley, Excelsior, River View, and the Silver Brick Mountain mines. Most of these, with the exception of a few small leased properties, are idle at the present time. None of the groups mentioned have reached a vertical depth of over 500 feet, and their aggregate production already exceeds \$2,000,000.

These veins are nearly vertical fissure or fracture planes, cutting through the gently tilted beds of blue-gray crystallized lime and dolomite. The limestone beds have been very much fractured and dolomitized, brecciated, and re-cemented together. The pay ore is uniformly high grade, averaging for the entire camp fully 40 per cent. lead, and one to three ounces of silver for each unit of lead. It is usually a mixture of galena, hard carbonate, and sand carbonate of lead, associated with chloride, sulphide and bromide of silver, manganese, carbonate of iron, and occasionally a little zinc.

The ore occurs in thin seams, lining the walls of the fissures, and occasionally makes into pockets and great irregular bonanza chambers of clean ore. One of these chambers on the Beardsley-Excelsior group produced over one-half million of dollars worth of silver and lead ore.

Although the arrangement is different, people familiar with the geology of Leadville, will recognize in the above brief outline, the principal elemental conditions of Colorado's most famous camp, with the single, but most important exception of the horizontal porphyry dikes.

The serrated, fractured and brecciated bluffs of Carboniferous lime and dolomite in which the principal lead mines are situated, and which are filled with a network of lead mineral manifestations, in their immediate vicinity, appear particularly devoid of porphyry. Yet their condition is such as might have been produced by the steady intrusion of igneous matter into their foundation layers, and the subsequent solfataric emanations that would be apt to follow it. And as a matter of fact, the belt of foot hills, flanking the lime formation, is underlaid for miles by at least two intrusive sheets of blocky quartz porphyry, or porphyrite, 10 to 50 feet thick, whose prevailing tints and conspicuous mineral constituents point almost conclusively to their origin in the main vent of similar igneous matter near the head of the canyon. They are exposed by occasional outcroppings in the small cross cutting streams that drain this double mountain uplift, and at one point the upper porphyry sheet is exposed within 300 feet of the lowest outcropping lime horizon, but its actual contact is obscured by debris.

If the fractured and altered condition of this lime belt, was brought by, and subsequent to, the intrusion of these porphyry sheets, then the prevalent mineralization unquestionably came from the same source. And these conditions point to a probable underlying resource of bedded contact bodies of silver-lead ores, that may prove to be of enormous extent and commercial importance.

This most interesting, and I might say, pronounced Leadville feature of this district, has apparently been entirely overlooked by the miners and engineers who have had charge of its development. No attempt has been made to open up the underside of these beds, or dikes of intrusive porphyry at any point. In fact they have never been touched, except at one place near the mouth of Bayhorse Canyon, where a small quarry was opened on the lower dike, for the purpose of extracting the desirable blocky building stone it afforded.

This lead belt is only one of several well defined courses of lead-silver bearing formations in Custer County. It is the most persistently mineralized however of any of them, and shows a variety of surface manifestations, that should prove a paradise for Colorado prospectors, familiar with the lead-silver bearing contact formations.

There are dozens of fine prospects that have been abandoned since the slump in silver, and some of them good mines, with considerable development. Seven miles south of Bayhorse, the Centennial and Homestake mines have been large producers of rich ore. These are contact veins between blue lime and steep pitching dikes of porphyry. At Clayton, 12 miles south of Bayhorse, the Ella mine carries a well defined fissure vein, in lime and quartzite, filled with carbonate of iron, and rich concentrations of gray copper ore. This mine had one pipe of steel galena ore, about 10 by 20 feet, that was followed down to water level, and produced over \$400,000 worth of silver-lead bullion.

Adjoining the Ella on the same strike, the Rob Roy Group has considerable development, exposing a large vein of 20 per cent. lead ore, worth 20 ounces in silver. This group has several parallel veins of iron and shows considerable sulphate of barite or heavy spar, that infallible blossom of rich ore among the Aspen mines, the probable importance of which does not seem to have been half appreciated in this district.

Three miles south of the Rob Roy on the east side of Squaw Creek, the Red Bird mine is located on a big zone of blocky blue lime, that carries a line of bold croppings and blowouts of carbonate of iron, plainly traced along the surface for six miles.

The Red Bird is developed to a depth of 400 feet, and a lateral extent of not to exceed 1,000 feet, by adit tunnels. The ore in this mine consists of hard and soft carbonate of lead and galena, well mixed with carbonate of iron and sufficient lime to

make it self-fluxing. It has already produced \$700,000 worth of lead-silver ore, that yielded an average value of not less than 30 per cent. lead and 30 ounces of silver per ton, a good deal of the ore running much higher. Six miners turned out 30 tons of ore a day for 90 days last summer, while the Company's smelter at Clayton was running.

On the opposite steep slope of a synclinal trough, that forms the bed of Squaw Creek, in what is probably the same lime horizon, the Saturday and Molly D Mines have shipped several hundred thousand dollars worth of ore, that averaged over 50 per cent. lead and 50 ounces in silver.

Continuing south about ten miles farther, on the opposite side of Salmon River, at the head of Slate Creek, the Silver Rule Mine was a bedded deposit of hard gray carbonate of lead. It has produced \$350,000 worth of ore, yielding 60 per cent. lead and 60 to 150 ounces of silver, together with \$5 to \$8 in gold. The importance of a system of narrow vertical fissures filled with granular quartz and a good sprinkling of the same high grade lead-silver ore, that terminates on the underside of the bedded vein seems to have been overlooked. The mine is now idle. These fissures are probably the fountain source of the bedded deposit, and their further exploration may develop a still more profitable resource of ore than that already mined.

A short distance still farther south of the Silver Rule, the Livingston Group of mines, consisting of seven claims, and owned by some Denver people, makes one of the most handsome showings of high-grade lead-silver ore in the State. This vein is in lime, slate, or shale, and associated with dikes of granular pyritiferous porphyry, which gives it every appearance of permanency. There is seven or eight hundred feet of development on this property, distributed in short tunnels, driven in on the ore and proving its continuity for over 2,000 feet in length. The pay-streak is from 6 inches to 3 feet wide of the same hard gray carbonate of lead, as that found in the Silver Rule mine. It gives average values of 50 to 70 per cent. lead, and 50 to 500 ounces in silver and \$5 to \$20 in gold. There have been several carloads of selected ore shipped from this mine that yielded over 60 per cent. lead and 300 ounces of silver per ton.

On the opposite side of the divide, two miles distant, the same Denver people own another property, which they call their low grade mine. This is a large vein of sand carbonate, and galena ore, associated with some zinc, and carries big strong shoots of clean ore, 2 to 8 feet wide, that yielded average values of 50 to 60 per cent lead and 20 to 40 ounces in silver.

The Salmon River range or aggregation of rough mountains and canyons, which divides the waters of Middle Fork from the main Salmon River, and extends from the head of Cape Horn Creek to Shoup, a distance of 75 miles in an air line, contains numerous districts and belts of mineral besides the one just described and their various mines have a bullion record of not less than \$50,000,000. Of this magnificent yield, fully 30 per cent was in gold, 15 per cent in silver and 5 per cent lead and copper.

The baser metals in this region have been avoided and neglected principally by reason of lack of transportation facilities. But if the present commercial magnificence of the United States continues, the extensive deposits of copper lead, iron and other useful metals here manifested will doubtless soon attract the attention of capitalists, and form the basis of large industrial enterprises.

The prevailing formation of this range is granite of varying types, from fine schisty gneiss to the coarsest bird's-eye variety, with porphyritically developed crystals of orthoclase feldspar of extraordinary size,—from 2 to 4 inches in the direction of their vertical axes. The prevailing color is gray, but in the old Loon Creek placer district, west of the great volcanic peaks of the Custer and Bonanza gold belt, there is a large area of country showing the deep pink variety similar to the Pike's Peak and Cripple Creek type.

Since Archean times this range has been subjected to an enormous amount of volcanic disturbance, which has produced a great variety of cosmic effects, from a simple fold to the intrusion of a succession of great laccolithic mountain peaks, filling whole districts with rich gold-bearing igneous rocks.

At one place in Lemhi County, there is evidence of the complete subsidence of the original summit of this grand old range, which for several miles is sunken into a narrow synclinal trough of coarse Archean granite, and now forms the bed of Big Creek, misnamed Napias Creek, on the map of the State of Idaho, recently issued by the U. S. Land Office.

This great earth movement resulted in a parallel mountain uplift, on both sides, eight to nine thousand feet high, capped with Silurian sediments, and produced lines of shearing and dynamic disturbance, together with igneous intrusions, which tapped a reservoir of copper and gold in the Blackbird District. This district promises to develop one of the most extensive and profitable resources of those metals ever discovered.

Besides gold, silver, copper, lead, and iron, there is a great variety of other useful metals and minerals in this region. Among these the writer has collected high grade specimens of cobalt, nickel, bismuth, tin, antimony, zinc and mercury ores; some rough crystals of sapphire; gem opals, worth \$10 per carat; fine specimens of fluor spar and cryolite, and a great profusion of garnets. Traces of platinum and palladium have also been found in some of the placer gravels.

The origin of these ores and metals is plainly manifested by modern solfataric action in hundreds of hot mineral springs, distributed over the entire length and breadth of the range, and in some places emanating directly from rich mineral bearing veins.

This is one of the best watered and timbered ranges in the West, and with the magic influence of railroad transportation, its future importance as a wealth producer can hardly be over-estimated.

A preliminary survey has been made by the Idaho Midland Railway Company, on a proposed line, to be run from Boise City, Idaho, to Butte, Montana. Should this line be built, and there is a very bright prospect for it at the present time, it will run down the Salmon River, along the east slope of this range its entire length, and be assured an immense tonnage of mineral freight right from the start.

The next legislature of Idaho would do much for the advancement and general welfare of the State by providing for a State Mineralogist and Mining Inspector, to take the place of the present office of Mine Inspector. And the position should be filled by a man of recognized ability, with sufficient salary and ample appropriation at his command. His duties should be, not only to inspect working mines, but to visit new camps, districts and discoveries, and make quarterly or annual reports of the mineral resources of the State, by districts, sections and counties. The interior mountain fastnesses of Idaho, contain rich volumes of mineral information, that the world should possess, and if presented under the authority of the government, it would result in bringing more capital to the State than any other method that could be devised.

CATALOGUES RECEIVED.

Kerosene Engine.

The Kerosene Engine here illustrated and made by August Mietz, 128-138 Mott St., New York City is becoming a very popular motor where gas is not available for a gas motor. These engines furnish a safe and reliable power and they are claimed to be perfectly safe, while insurance companies do not object to their installation. They are operated with ordinary kerosene oil and can therefore be used wherever this oil is procurable. The makers state that they consume about 1 pint per horsepower per hour, the amount being automatically regulated to the power used by a governor, the motor maintaining a uniform speed. The automatic igniter does away with an electric spark or tube igniter and thus any source of trouble from internal combustion is avoided; this feature combined with the constructional simplicity of the engine renders it particularly useful and reliable even in the hands of untrained attendants. An enclosed crank shaft renders the engine dust proof. It is also extremely rigid, self lubricating and there is no odor from the piston. The oil for the crank drops into the groove on top of the rod whence it finds its way along to the pin and these automatic oiling devices operate only when the engine is running. When the engine is to be stopped it is only necessary to throw up a small finger which regulates the oil supply.

The advantages claimed for these motors by the makers over steam and other forms are as follows: They require no engineer, no water is consumed, there is no handling of coal or ashes and they can be very quickly started and require no attention except

oiling. They are said to be strong and more durable than a steam engine and boiler and take up less room. Blueprints and catalogues can be obtained from the maker, Mr. August Mietz at the address given above.

COMPRESSED-AIR HAULAGE-PLANT

At No. 6 Colliery of the Susquehanna Coal Company, Glen Lyon, Pennsylvania.

By J. H. Bowden, Wilkes-Barre, Pa.*

The shaft-plant here described was put in operation in September, 1895, and the No. 6 slope-motor was started in May, 1896.

The plant comprises: One Norwalk three-stage compressor 12 $\frac{1}{2}$, 9 $\frac{1}{2}$ and 5 in. diameters of air- and 20 in. diameter of steam-cylinder, all 24 in. stroke; capacity at 100 revolutions, 296 cu. ft. of free air per minute, compressed to 600 lbs. per sq. in. A main pipe, 5 in. diameter, 4,380 ft. long, with five charging stations in No. 6 shaft, and a branch of 3 in. pipe, 3,100 ft. long, with three charging stations, in No. 6 slope. These pipes on each line charge a Porter compressed-air motor, with 7 $\times$ 14 in. cylinders, and four 24 in. drivers, weighing about eight tons, with a tank capacity of 130 cu. ft. of air at 550 lbs. pressure in the main tank, reduced to 160 lbs. in the 8-in. auxiliary tank of 4.2 cu. ft. capacity, supplying the cylinders. The No. 6 shaft run averages 4,000 ft. each way on grades of $\frac{1}{2}$ to 2 $\frac{1}{2}$ per cent., and averaging close to one per cent. in favor of the loaded cars. The No. 6 slope run averages 2,100 ft. with nearly the same grades. The mine cars weigh 2,800 lbs. empty, and about 9,800 lbs. loaded, and are hauled in trips of 12 to 20, averaging about 15 cars. The shaft-motor now hauls about 355, and the slope-motor 320 cars per day of 10 hours, replacing in the shaft 17 mules, and in the slope 15 mules, or, in all, 32 mules, against 27 replaced in 1896.

The average daily car- and ton-mileage of each motor was as follows:

	Cars Hauled.		
	1896.	1897.	1898.
No. 6 Shaft-motor.	355	347.4	356
	Tons Hauled One Mile.		
	1896.	1897.	1898.
Empty, in	336	330	338
Loaded, out	1,180	1,155	1,183
Total	1,516	1,485	1,521
Net load	844	825	845
	Cars Hauled.		
	1896.	1897.	1898.
No. 6 Slope-motor.	288	288.7	319.2
	Tons Hauled One Mile.		
	1896.	1897.	1898.
Empty, in	143	144	160
Loaded, out	501	504	540
Total	644	648	720
Net load	358	360	400
Total for both motors, gross (including empty cars returned)			
	1896.	1897.	1898.
	2,160	2,133	2,241
Net load			
	1,202	1,185	1,245

The use of steam and air in operating the compressor and motor was found by test to be:

Steam.

Indicated horsepower at 181 revolutions of compressor	150 H. P.
Steam-consumption per H. P. per hour, from cards	34 lbs.
Steam-consumption per hour	5,100 lbs.
Steam-consumption per hour including condensation in line	5,200 lbs.
Boiler horsepower required	174 B. H. P.
Evaporation per lb. of coal (cylinder boilers)	5 lbs.
Coal required per hour	1,040 lbs.
Coal required per day, 10 hours	10,400 lbs. 4.65 tons.
Cost of fuel and firing per day (10 hours) 4.65 tons, at 50c.	\$2.32

Air.

Compressor Capacity.—The free air compressed per revolution of compressor is 2.96 cu. ft., according to the calculation of the Norwalk Iron Works Co., no allowance being made for leakage. The compressor works 12 hours per day; the motors 10 hours.

	Cu. Ft.
Free air per minute at rated speed of 100 revolutions	296
Free air per minute at actual speed of 131 revolutions	387.8
Free air per day 12 hours at rated speed of 100 revolutions	213,120
Free air per day 12 hours at actual speed of 131 revolutions	279,216

Capacity of Air-Mains Used as Reservoirs.—The capacity of the 5-in. line, 4,380 ft. long, is 608 cu. ft.; and that of the 3-in. line, 3,100 ft. long, is 159 cu. ft., making the total for both lines 767 cu. ft.

At 600 lbs. pressure these lines hold 32,505 cu. ft. of free air. The capacity of the main and auxiliary tanks is 134.6 cu. ft. At 508 lbs. pressure (at which they will equalize with the main, start-

ing to charge at 600 lbs.), this is equivalent to 4,845 cu. ft. free air.

Leakage of Air-Mains.—In standing 12 hours the pressure falls from 550 to 350 lbs., and of free air, 11,688 cu. ft., or 974 cu. ft. per hour, are lost. The proportion of this leakage to the total air compressed is 4.18 per cent.

Air Used by Motors.—According to a test made March 29, 1900, the amount of air used for the given amount of work was as follows:

	Shaft-Motor.		Slope Motor.
	No. 2 Plane.	No. 3 Plane.	
Number of trips empty	8	10	16
Number of trips loaded	8	10	15
Average No. of cars per trip, empty	15.83	12.7	11.4
Average No. of cars per trip, loaded	18	13	11.3
Average cu. ft. of free air per trip, empty	1,724	5,686	1,230
Average cu. ft. of free air per trip, loaded	1,631	1,898	599
Average cu. ft. of free air per round trip	3,855	7,584	1,829

Summary of Day's Work in 1898.—At shaft No. 6, 356 cars were hauled per day; namely, from No. 2 plane, 6 trips of 15 cars each, using 20,130 cu. ft. of free air, and from No. 3 plane, 20 trips, averaging 13.2 cars each, using 151,680 cu. ft. of free air. The work at Slope No. 6 was 320 cars per day in 28 trips, averaging 11.4 cars each, and using 51,212 cu. ft. of free air, making a total for 676 cars of 223,022 cu. ft. of free air. The amount of free air apparently compressed for this work was 279,216 cu. ft., of which 83.4 per cent. is accounted for, leaving 16.6 per cent. for leakage and slip in the compressor, leakage in air-lines, and changes in temperature.

Air Used Per Ton-Mile.—The average volume of free air used per ton-mile is as follows:

	Cu. Ft.
No. 6 shaft-motor, gross	113
No. 6 shaft-motor, net	203
No. 6 slope-motor, gross	71
No. 6 slope-motor, net	128
Both motors, gross	100
Both motors, net	180

The greater quantity of air used by the shaft- as compared with the slope-motor is due to the heavier curves and the switching required, especially at No. 2 plane, where a portion of the trip is frequently left.

Cost of Plant.—The cost of plant, not including steam boilers, was as follows:

Compressor	\$2,880.00
Extras for compressor-repairs	75.75
Shaft-motor	2,743.63
Slope-motor	2,918.20
Extras for motor repairs	207.98
Air-connections, 5-in. line (6,000 ft.)	2,914.32
Air-connections, 3-in. line (4,000 ft.)	1,240.46
Steam-connections to compressor	278.27
Material for compressor-foundations and house, and air-washing box	295.27
Labor on compressor-house and foundations, and 5-in. line, and installing shaft-motor	1,183.01
Labor on 3-in. line and installing slope-motor	46.95
Foster equalizing-valves	872.21
Total cost of plant	\$15,156.03

Cost of Operation.—The operating expenses are shown in the following table:

	1897 (179 days worked).		1898 (160 days worked).	
	Per Day.	Per Year.	Per Day.	Per Year.
2 Motor engineers, at \$2.10	\$4.20	\$751.50	\$4.20	\$672.00
2 Brakemen, at \$1.60	3.20	572.80	3.20	512.00
1 Engineer for compressor, at \$2.32	1.16	207.64	1.16	185.60
Oil for compressor	.67	119.49	.47	75.94
Oil for motors	.25	45.08	.25	40.94
Repairs for compressors (material)	.10	18.76	.48	76.06
Repairs for compressors (labor)	.06	10.38	.09	15.22
Repairs for motors (material)	.16	28.78	.51	81.06
Repairs for motors (labor)	.18	32.77	.23	36.87
Steam for compressor (150 H. P.), fuel and firing	2.32	415.28	2.32	371.20
Total operating-expenses	\$12.30	\$2,202.78	\$12.91	\$2,066.93

Total Cost Including Fixed Charges.—The total actual cost in the two periods mentioned was therefore, for the two motors (one-half to each), in 1897, per day, \$22.23, and for the whole period, \$3,979.38; and in 1898, per day, \$24.01, and for the whole period, \$3,843.83. Taking the figures of 1897 as a basis, and

*A paper read before Canadian Meeting of The American Institute of Mining Engineers, August, 1900.

assuming 300 days of work in a year (with consequent saving in certain items of fixed charges, superintendence, etc.), it is estimated that the total cost would be \$18.22 per day, or \$5,466.60 per year. A similar calculation, based upon the figures of 1898, gives \$18.83 per day, or \$5,649.60 per year.

Fixed Charges.—The fixed charges are as follows:

	1897 (179 days worked).		1898 (160 days worked).	
	Per Day.	Per Year.	Per Day.	Per Year.
Interest, repairs and depreciation of 174-H. P. boilers	\$1.46	\$261.00	\$1.63	\$261.00

At the average rate of saving for 1897 and 1898, the entire cost of the plant would be saved in 361 working days.

The capacity of the shaft-motor is equal to fully double its present work, and the slope-motor is working at but about one-third of its capacity, while the compressor is doing all that it can, and a second one was ordered April 7, 1900. To operate the plant to the full capacity of both compressors, which, under the present conditions would be about 4,500 ton-miles gross or 2,500 net per day for 300 days per year, would bring the cost of operation, including fixed charges, to about \$24.60 per day, or $\frac{3}{10}$ of a cent per ton-mile gross and $\frac{3}{10}$ of a cent per ton-mile net load. If all the work could be done by one motor under the conditions of No. 6 shaft, up to the capacity of the compressor, for 300 days per year, using only one crew, the cost of plant would approximate \$11,000, and the operating expenses, including fixed charges, would be \$10.86 per day for 2,400 gross ton-miles, or $\frac{1}{10}$ of a cent per gross ton-mile and $\frac{1}{10}$ of a cent per net ton-mile.

A further reduction of cost would result from reheating the air at the motor, by passing it through water at the temperature of steam at 90 pounds pressure, by which method tests have shown a gain of about 50 per cent. in air-economy. It is probable that by this means one motor could be run to its full capacity (about 3,000 gross ton-miles per day) with one compressor, at a total cost of \$10.80 per day, or $\frac{3}{10}$ of a cent per gross ton-mile, for 300 days' work per year, the saving of $\frac{1}{10}$ of a cent per gross ton-mile, or about 20 per cent. over the last mentioned conditions being due only to the greater air economy; the fixed charges and labor-cost remaining practically the same.

For a detailed description of this plant, with illustrations, those who are specially interested are referred to the *Colliery Engineer and Metal Miner*, Scranton, Pa., for May, 1898, and to the Report for 1895 of the Pennsylvania Bureau of Mines, pp. 104 to 110.

Competition With American Kerosene in Australia.

Consul-General Bray, of Melbourne, under date of July 27, 1900, says he is reliably informed that the Shell Trading and Transport Company, of London, England, has secured sites in Melbourne and Sydney on which it will erect large refining works, the product of which will, it is anticipated, compete very keenly with American oil in those markets. The clipping reads:

At the meeting of the company held in London on the 21st of June, regarding the extension of the business to the colonies and other centers, the chairman said:

"In view of the very large supplies coming to us for marketing, it has been necessary, in the opinion of the directors, to widely extend the field of the company's operations, and accordingly arrangements have been concluded to extend the business to many new ports in China, and we still hope that, in spite of the trouble now prevailing there, we shall see the company's oil retailed in the streets of Peking before the end of the year. It is a matter of congratulation to the directors that they have been able to conclude arrangements with Messrs. Julius Weil to act as their agents in the Cape, this firm possessing unrivaled distributing media, and as soon as the war is over installations will be erected at the principal towns in the colony. Excellent sites have been secured in Melbourne and Sydney, and arrangements have also been made to extend this company's business to Adelaide, Brisbane, and New Zealand, the quality of the kerosene now being produced rendering it exceptionally suitable for the Australian markets. After great difficulties, we have also succeeded in obtaining permission to erect tank storage at the principal ports in Java, and sites have been acquired, as also at Zanzibar and Mombassa. The shareholders will thus see that the business is still in its infancy, and the directors consider it sound policy to have the company's business as widespread as possible, so that in case of competition, they may be free to choose the most remunerative markets throughout the world in which to place their products."

The chairman also stated that large sums have been invested by the company in purchasing and developing their fields in Borneo, and they have acquired an oil-bearing territory of about 460 square miles in extent, with an oil production which has exceeded 1,000 tons a day, and a refinery capable of dealing, when complete, with 3,000 tons of crude oil daily. The actual portion at work was handling 2,500 tons of crude oil per week, and by the end of August a second bench of stills would be at work, when the refinery could deal with 5,000 tons of crude oil weekly, and every effort would be made to complete the other two benches of stills already provided and awaiting erection. When the whole of the four benches of the refinery are at work, the income from Borneo products alone is expected to exceed £1,000,000 per annum. This is, of course, provided that the present supply of oil continues, and markets are found, and that present prices for the various products upon which the estimate is based are maintained.

THE PARIS EXHIBIT

Of the Ingersoll-Sergeant Drill Company—An Extensive Exhibit of Mining and Compressed Air Machinery.

One of the most extensive exhibits from the United States at the Paris Exposition is that of the Ingersoll-Sergeant Drill Co., of New York City, which company has exhibits of its air compressing, mining, tunneling, and quarrying machinery in three places. On the Champ de Mars, in the Palace of Machinery and Electricity, it has established its headquarters in the midst of the United States machinery section. Here, one of the company's Class "H" compressors is in operation, supplying air for all the pneumatic tool companies' exhibits and the tubular despatch of the Batcheller Pneumatic Tube Co. This compressor has duplex steam and compound air cylinders. The former are 12 inches by 12 inch stroke, and the latter 18 inches diameter for low pressure, 12 inches diameter for high pressure, and 12 inch stroke. The engine is of the well known Tangye frame type, mounted on a solid base, which contains a special cooler through which the air passes on its way from the low to the high pressure cylinder. In this way, its temperature is reduced to about that of running water, and the work required to compress a given volume of air is considerably reduced. A section of the air cylinder of this machine is shown by (Fig. 1). It will be seen that the cylinders are jacketed all around and in the heads, by which arrangement the air is cooled and the working parts kept at a low temperature.

Adjustable cut-offs are used for the steam cylinders, with a range of from $\frac{1}{4}$ to $\frac{3}{4}$ cut-off, while an automatic regulator, which is attached to the air receiver or reservoir, maintains a constant air pressure, cutting off the steam supply or opening up to a greater or less extent, as the air pressure runs up or drops below the set pressure. In this case the compressor regulates to within 1 to $1\frac{1}{2}$ lbs., when set to 100 lbs.

In Group IV, Civil Engineering and Transportation, the Ingersoll-Sergeant Co. also exhibited a small motor-driven compressor and some interesting models. This compressor has a

FIG. 2. INGERSOLL-SERGEANT CLASS "A" AIR COMPRESSOR.

single air cylinder, 6 by 6 inches. It has on its base a 5 H. P. General Electric Company's direct current motor, to which it is geared with a single reduction. When running at full speed, about 150 revolutions per minute, it has a capacity of 26 cu. ft. per minute, to a pressure of 50 lbs. per square inch. This machine was installed by the U. S. Commission to furnish air for operating models of the machinery used in the excavation of the Chicago

Drainage Canal, which are here shown. Among these machines are found four little working models made to $\frac{1}{4}$ scale, and illustrating in a most pleasing way the construction of a Bar Channeler, a Track Channeler, both being machines for cutting out work in quarries, canals or railway cuts, and also showing a standard rock drill and one of the company's Class "A" compressors. (Fig. 2.)

There is, in addition, a full sized pneumatic or compressed air coal cutter, such as is coming into extensive use in the United States, and an interesting series of photographs showing other apparatus manufactured by this concern. The main exhibit is,

however, at Vincennes, where it occupies a space 41 by 34 $\frac{1}{2}$ ft., or about 1,400 sq. ft., in a prominent position. Here it has two compressors and all of its mining and quarrying apparatus in the form of rock drills, coal cutters, and channeling apparatus.

The largest compressor (Fig. 3) occupying one side, is a horizontal-cross-compound Corliss type, with steam cylinders 12 and 22 inches and a 30 inch stroke. The low pressure air cylinder is 16 $\frac{1}{2}$ $\times$ 30 inches, and the high pressure 10 $\frac{1}{2}$ $\times$ 30 inches. Between them is placed a Sergeant Vertical Inter-cooler. This device effectually removes the heat resulting from compression in the first cylinder, and at the same time acts as a receiver or reservoir from which the high pressure

cylinder draws. The low pressure cylinder has an exceedingly novel and satisfactory form of inlet and discharge valve devised by Mr. H. S. Sergeant, the engineer of the company. This is a type of mechanical valve which avoids the difficulties inherent with air compressor valves which have rigid rod connections, and it depends upon compressed air for its operation. In this way, a perfect adjustment can be obtained, and cards taken from the cylinder are as regular as those obtained from a well adjusted Corliss steam cylinder.

The high pressure steam cylinder is provided with the well known Sergeant system of piston inlet valves. This type, has a higher volumetric efficiency than any other form of compressor cylinder, owing to the remarkably small clearance volume necessary, and to the large valve openings and the rapid opening and closing of valves resulting from the peculiar construction of the valves themselves. The piston is hollow and has a hollow extension at the back end, which passes out through a suitable stuffing box in the head of the cylinder. The piston, has in either face, a circular slot concentric with the piston rod. These slots are closed by a ring, which, in a cross section, resembles a letter "T." No springs are needed to open or close these valves, as the inertia resulting from the movement of the piston throws them open or closed at the proper moment. It will be seen that this form of valve admits of a remarkably small clearance. In addition, the constant inrush of cold air always passing in one direction helps to prevent excessive heating of the piston, while the water jacketed cylinder and heads hold their temperature down to a low point.

NO. 3. INGERSOLL-SERGEANT CLASS "C" COMPRESSOR.

single air cylinder, 6 by 6 inches. It has on its base a 5 H. P. General Electric Company's direct current motor, to which it is geared with a single reduction. When running at full speed, about 150 revolutions per minute, it has a capacity of 26 cu. ft. per minute, to a pressure of 50 lbs. per square inch. This machine was installed by the U. S. Commission to furnish air for operating models of the machinery used in the excavation of the Chicago

Both compressors discharge into a receiver which resembles the inter-cooler already described. This again reduces the temperature of the air to that of running water, and, as a result, precipitates nearly all of the moisture contained in the air.

From this reservoir, a 4 inch pipe line is run straight away for over 900 feet to the Palace of Civil Engineering and Transportation. The air supplied by this line runs two Baldwin locomotives, the New York Air Brake Company's exhibit, that of the Westinghouse Air Brake Co., Westinghouse Signal System, the Standard Signal System, and other exhibits.

A second and smaller line runs the entire length of the Machinery Annex Building, which taps off to the Q. & C. Pneumatic Tool Co., the Standard Pneumatic Tool Co., the Chicago Pneumatic Tool Co., the Jeffrey Manufacturing Co., the Ball Engine Co., and the Bullock Diamond Drill Co.

Both compressors take steam at from 100 to 120 lbs. and furnish air at from 100 to 105 lbs., the two machines having a volume of about 1,000 cubic feet of free air per minute.

It is interesting to note that the compressors of this company were the first apparatus in the entire American machinery section to operate on "Opening Day," April 14th, excepting the boilers installed by the Commission. They were also among the very first steam engines in the entire Paris Exposition to run with steam from the Administration mains.

Coming now to the mining machinery exhibited by this company, we first notice a large Track Channeler; in other words, a machine running on a track and intended for cutting a long, narrow vertical slot in rock of any sort. Thirty-five of these were used on the Chicago Drainage Canal, where for miles they cut vertically through hard or uncertain rock to a depth of from 24 to 36 ft. in three steps of 12 ft. each. This machine consists of a fair sized vertical tubular boiler mounted on a heavy frame, in turn supported by four flanged wheels, which run on a track made in sections. At one side and supported on a substantial bracket frame are the cylinder guides, valves and controlling mechanism. Steam passes over from the boiler through flexible connections to the cylinder and causes the piston to reciprocate, rapidly raising and driving down the cutting bars which are clamped to the guide chuck on the end of the piston rod.

The cutting points are under absolute control of the operator, who can strike hard, rapid blows or light slow ones, or he can cause the cutting to occur at the upper or lower part of the stroke. The single lever which shifts the machine along the track is also within easy reach, as are also all the lubricators, adjustments, etc. Machines of this type and make have cut as much as 375 square feet in 10 hours, although the average on large work is from 160 to 175 square feet for the same time.

Another interesting machine intended for quarries and places where the output would not warrant the expense of the large machine just described, is the Bar Channeler (Fig. 4). Briefly, it consists of a frame mounted on four adjustable legs. This frame has two long cylindrical slides, on which are mounted a carriage holding a powerful air or steam drill and a small engine which feeds the carriage back and forth along the frame. In operation, the machine is set up, the frame given the desired inclination, which may be varied from vertical through all angles to horizontal, and the drill and shifting mechanism is started. This combination of rapid and powerful blows from the cutting points, and the side movement of the feed result in a narrow slot the length of the frame and $7\frac{1}{2}$ feet deep, which is so smooth, that stone cut this way needs only facing to be ready for use in buildings or for other purposes.

The Standard Rock Drills, of which the company has several of the small and medium sizes set up for operation, are mounted on the Sergeant Universal Tripod, which permits a rapid adjustment in any direction and which, while exceedingly light in weight, is unusually rigid owing to the method of construction and clamping of the parts. Other forms of mountings, for shafts and tunnels are also shown. This company yearly produces over 2,500 of these drills, of different sizes, and it has already sold over 30,000 drills of all sorts.

A Pneumatic Coal Cutter, of which the company is turning out about 1,000 each year, and a type which is a novelty in Europe, is also shown. In a general way, this machine may be compared with a wheelbarrow, from the front of which projects the cutting tool. The operator holds the handles and guides the machine forward or from side to side, and thus cuts under the coal, which is then broken down. The claims for this type are many, and not the least important of these are its extreme simplicity, rapid and large output, the introduction of an appreciable amount of clean fresh air into the heading and the absence of powdering, which always results from the use of milling or saw cutters. Also the machine is very compact and light, and is inexpensive.

A variety of small parts, such as drills, drill sharpening tools, cutters, clamps, hoses, etc., complete this exhibit, which, as already stated, is the most extensive mining and air compressor exhibit from the United States, if not from any country exhibiting at the Paris Exposition.

Ocean Lumber Rafts.

The announcement that an immense pile raft is now under construction on Puget Sound to be towed to Japan serves to call attention to one of the most interesting industries on the Pacific coast, and one in which the shipping interests are directly interested. The rafts constructed by Capt. H. R. Robertson on the Columbia River and Puget Sound during the past year or two are not only the largest of the kind ever built, but are in many respects of unique construction. Capt. Robertson some fifteen

years ago commenced the building of these rafts on the Atlantic coast, but learning of the immense quantity of piles on the Pacific coast decided to transfer his operations, and has lately established a permanent raft building plant at West Seattle, Wash. It is anticipated that henceforth three or four rafts of the largest size will be turned out each year.

The average raft constructed by this company is 625 feet in length, 55 feet beam, 38 feet depth and 24 feet draught of water. The hull and cargo of each comprises some 11,000 piles and upwards. These raft structures have all the appearance of a whaleback, being pointed at each end, with a hull outlined and built to buffet the heaviest seas with the safety of a sailing vessel. Indeed the builders claim that if fitted with rudder and canvas they could make very fair progress on their

own account. The 11,000 piles which are worked into a raft of this kind average 60 feet each in length and the huge structure thus contains in the neighborhood of 660,000 lineal feet or about eleven times the pile cargo of a fair-sized sailing vessel.

The fact that one of these immense rafts may be taken to its destination with average safety and without the expense of employees beyond those on the towing steamer is an additional point in their favor from an economic standpoint.—Indeed the only expense in building and marketing the raft is found in the first cost of the cradle; the services of about a dozen employees being required for three months, the time ordinarily required for construction; and the outlay for some 5,000 feet of chain which is utilized to hold the piles together in their original form. The cost of the entire structure including the cradle, does not exceed \$5,000. The majority of the rafts which have heretofore been constructed have been towed to San Francisco and sold. The prices which they have brought would seem to insure an immense profit for the builders, but possibly the figures are not unduly high considering the risk involved. Shipping interests in the Pacific have carried on some agitation against these immense rafts on the ground that the piles if broken up and scattered in a storm would prove a serious menace to navigation, but no active steps have been taken to restrict their construction. The raft builders, on the other hand, declare that they have taken precautions to reduce the danger to a minimum. The chains wrapping the bulk are two inches in diameter, and in addition to being placed only six feet apart from end to end are interwoven and bound in the staunchest possible manner, so that nothing but the severest storm could possibly disrupt the mass.—*Marine Engineering*, September, 1900.

FIG. 4. STARTING A QUARRY WITH A BAR CHANNELER.

EXAMINATION QUESTIONS

For

Mine Managers, Mine Foremen, Fire Bosses, Etc.

EDITED BY J. T. BEARD, C. E., E. M.

Answers to the questions given by the several Boards of Examiners will be made as concise as possible, and in case the same question has been answered in the current volume the reader will be referred to the answer already given. When they will throw additional light upon the subject of the question, short notes of explanation will be placed in brackets in connection with the answer proper.

Many of the questions suggest principles that can be more satisfactorily discussed in a separate article than is advisable in an answer to an examination question. Such articles will be published in this department as a help to those preparing themselves for examinations.

All persons interested are invited to send to MINES AND MINERALS copies of questions asked at any examination as soon as possible after the examination is held.

Mine Foremen's Examination for the 3rd and 4th Anthracite Districts of Pennsylvania, June, 1900.

QUES. 1.—Give name, age, place of birth and post-office address.

QUES. 2.—Give a brief description of your service in the anthracite mines. Name the mines and give length of time employed in each.

QUES. 3.—What are the requirements of the Mine Law regarding the examinations of mines?

ANS.—Rules 4, 5 and 6 of Article XII of the Anthracite Mine Law of Pennsylvania read as follows:

RULE 4.—All accessible parts of an abandoned portion of a mine in which explosive gases have been found shall be carefully examined by the mine foreman or his assistants at least once a week and all danger found existing therein shall be immediately removed. A report of said examination shall be recorded in a book kept at the colliery for that purpose and signed by the person making the same.

RULE 5.—In mines generating explosive gases, the mine foreman or his assistant shall make a careful examination every morning of all working places and travelling roads, and all other places which might endanger the safety of the workmen, before the workmen shall enter the mine, and such examination shall be made with a safety-lamp within three (3) hours at most before time for commencing work, and a workman shall not enter the mine or his working place until the said mine or part thereof, and working place are reported to be safe. Every report shall be recorded without delay in a book which shall be kept at the colliery for the purpose and shall be signed by the person making the examination.

RULE 6.—The person who makes said examination shall establish proof of the same by marking plainly the date thereof at the face of each working place and all other places examined.

QUES. 4.—What is the maximum pitch up which you would work breasts with roads, and what methods would you adopt in steeper pitches? Give a full description.

ANS.—When the pitch of the seam is from 5° to 10°, the car may be taken to the face and loaded by driving the rooms across the pitch, or at an angle with the level or gangway. This reduces the grade of the track in the rooms. When the inclination of the seam is still greater, buggies are sometimes used, the track being built upon the refuse of the seam and raised at its lower end, where a dump is arranged by which the coal is dumped from the buggy

FIG. 1.

into the mine car ready to receive it. Where the coal is soft, this method cannot be used. It is employed on pitches not exceeding 15° or 18° in thick seams.

Seams pitching more than 15° are usually worked by chutes or self-acting inclines. When the pitch is less than 30° sheet iron is usually laid in the chute as a floor, to enable the coal to slide more easily; but on inclinations of less than 20 per cent. it is usually necessary to push the coal down the chute, as it does not

slide readily. On pitches steeper than 30° sheet iron is not necessary, as the coal will slide without it. Fig. 1 shows, in plan A and section B, an arrangement of the breasts, chutes, and manways, and the position of the gangway and air-course at the roof of the seam, in thick, steep-pitching beds. This position of the gangway and air-course secures a better inclination of the loading chute and manways, and presents less danger from squeeze. In the figure, *g* is the gangway and *m* the manway, dividing at the floor of the seam into two branches *s, s*, which lead to either breast. At this point, or slightly below it, a small cross-cut *d* is driven up to the airway *c*. This is bratticed off and used only in case of need, as the air is regularly conducted up one breast manway and down the other side to the highest cross-cut and thence to the next breast. Brattices with small doors are also placed in the manways to keep the air from taking a short circuit through the manways. Small manways are bratticed off the side of each loading chute for the use of the loaders.

Self-acting inclines are used sometimes upon steep pitches in preference to chutes. In this case, gangways are usually driven to the full rise and rooms set off on the strike from these, buggies being used in the rooms to convey the coal from the face to the incline.

QUES. 5.—At what points in a colliery does the law require safety-blocks?

ANS.—Rule 50 of Article XII of the Anthracite Mine Law of Pennsylvania reads as follows:

RULE 50.—Safety-blocks or some other device for the purpose of preventing cars from falling into a shaft or running away on a slope or plane, shall be placed at or near the head of every shaft, slope, or plane, and said safety-blocks or other device must be maintained in good working order.

QUES. 6.—Give name and composition of the dangerous gases of coal mines, and state the conditions under which the presence of the various gases may be expected, and how may each be detected.

ANS.—All gases in mine workings are dangerous when allowed to accumulate to any considerable amount. The gases commonly occurring in mines are: marsh gas or light carburetted hydrogen (CH_4), carbonic acid gas or blackdamp (CO_2), carbonic oxide gas or whitedamp (CO), sulphureted hydrogen gas or stinkdamp (H_2S). (These gases are fully described in the article "Mine Gases, Their Occurrence, Properties and Effects," page 275, MINES AND MINERALS, January, 1900.)

The conditions which give rise to the presence of marsh gas are always found in the working of a gaseous seam of coal; in the exposure of a large amount of fresh coal at the working face, or a heavy fall of roof, which may liberate a large amount of gas contained in the roof strata; also in the presence of feeders, or pockets of gas in the coal seam itself or the contiguous strata.

The presence of carbonic acid gas may be expected in dip workings or low portions of a large mine where there is a considerable extent of abandoned workings. This gas being heavier than air will always accumulate in the lower workings and passageways of mines where the ventilation is at all sluggish.

The presence of carbonic oxide gas may be expected in connection with abandoned workings, or the workings of mines where the ventilation is insufficient. The formation of this gas is due largely to the slow combustion of the slack and fine coal in the waste places of the mine where there is a limited supply of air.

The presence of sulphureted hydrogen gas may be expected in the working of coal seams containing a considerable amount of iron pyrites. The decomposition of the pyrites results in the formation of this gas. The gas is liable to occur frequently in the underlying strata and clays of coal seams containing pyrites.

The detection of marsh gas is accomplished by observing the effects of the gas upon the flame of a safety lamp. Usually the flame of the lamp is first lowered to a small, uniform size. The lamp is then cautiously lifted toward the roof to where an accumulation of gas is suspected and the flame carefully watched for the first appearance of a flame cap. In the presence of a small percentage of marsh gas the flame of the lamp is surmounted by a light blue flame cap. When a larger percentage of gas is present this cap is extended, and the height of the cap is always an indication of the percentage of gas present in the mixture. When the mixture approaches the explosive limit the flame is very much enlarged, and in the use of the normal lamp flame for testing the flame here becomes of a waving spindle shape. Beyond this point any increase of gas is followed by sharp cracklings and snappings of the flame, and slight explosions in the lamp.

The presence of carbonic acid gas is indicated by the dimness of the lamps, and the total extinguishing of the flame when a sufficient amount of this gas is present.

In carbonic oxide gas the lamp continues to burn brightly, the flame of the lamp, however, is lengthened and reaches upward in a slim, tapering blaze, often surmounted by a bluish tip, which is, however, difficult to observe on account of the luminous body of the flame.

Sulphureted hydrogen gas is detected by its strong smell, which resembles that of rotten eggs, from which it has received the name stinkdamp, by miners.

Ques. 7.—How would you proceed to remove a body of CH_4 from a series of breasts having a pitch of 30° , which had been filled with the gas during a stoppage of the fan?

Ans.—This question is fully answered in reply to Ques. 589, page 25, MINES AND MINERALS, August, 1900. See, also, article, "Removing a Body of Gas From Mine Workings," page 88, MINES AND MINERALS, September, 1900; and Ques. 8, page 377, March, 1900.

Ques. 8.—If you had your choice of the following intake airways, one 10 ft. $\times$ 10 ft., one 5 ft. $\times$ 20 ft., or two 5 ft. $\times$ 10 ft., which would you prefer, and why?

Ans.—The airway that would pass the largest quantity of air with the same expenditure of power would be preferable. The expression for the quantity of air passing in any given airway

under a given power is $q = a\sqrt{\frac{u}{ks}}$. Now, assuming the power and the length of the airways to be the same in each case, the quantity of air in circulation will vary as the expression $\frac{a}{\sqrt{s}}$, in

which a is the area (sq. ft.), and s the perimeter (ft.) of any airway. Substituting the given values, in each case, in this expression, we have for the relative quantities of air in circulation:

10 ft. $\times$ 10 ft. airway, q varies as $\frac{10 \times 10}{\sqrt{2(10+10)}} = \frac{100}{\sqrt{40}} = 29.24$ cu. ft.,

5 ft. $\times$ 20 ft. airway, q varies as $\frac{5 \times 20}{\sqrt{2(5+20)}} = \frac{100}{\sqrt{50}} = 27.14$ cu. ft.,

5 ft. $\times$ 10 ft. airways, q varies as $\frac{2 \times 5 \times 10}{\sqrt{2 \times 2(5+10)}} = \frac{100}{\sqrt{60}} = 25.54$ cu. ft.

The first of these airways will therefore give the largest quantity of air for the same power, and for this reason would be the one to be preferred.

Ques. 9.—In an airway 9 feet wide at the top, 12 feet at the bottom, and 9 feet high, the air having a velocity of 300 feet per minute, what quantity of air is passing per minute?

Ans. $q = av = \frac{9(9+12)}{2} \times 300 = 94.5 \times 300 = 28,350$ cu. ft. per minute.

Ques. 10.—What is meant by the terms ventilating pressure, water gauge, and resistance of air?

Ans.—The term *ventilating pressure* refers to the pressure producing ventilation. This is the total pressure upon the airway as indicated by the expression pa . The *unit of ventilating pressure*, or the pressure per square foot of area, producing ventilation, is, however, often spoken of as the ventilating pressure, in which case pa is the *total pressure*. [The ventilating pressure (pa) is always equal to the resistance of the mine or airway, since it is this resistance that causes the pressure.]

The water gauge is a glass tube bent in the form of the letter U and having two open ends. Water is placed in the bend of the tube, and one of the open ends is extended and bent over so as to pass through a hole in a door or brattice to which the instrument is attached in the mine. A small hole is bored in a door or brattice located between airways in which there is a difference of ventilating pressure. The two ends are thus subject to different pressures, the pressure upon the intake always being greater than that upon the return airway. This causes the water to sink in the arm of the water gauge open to the intake, and to rise a corresponding amount in the other arm. This difference of level is read from the scale on the face of the gauge and the term "water gauge" is frequently applied to this reading. [The use of the *water gauge* has been fully described in reply to Ques. 30, Page 273, MINES AND MINERALS, January, 1900.]

The term *resistance* as applied to the circulation of air in an airway, refers to the friction developed by the passing of the air current through the airway. The rubbing of the air upon the sides, top, and bottom, of the airway causes friction which produces a certain resistance to the passage of the current. [This resistance is therefore proportional to the extent of the rubbing surfaces. It also depends upon the velocity of the current, being proportional to the square of that velocity. This is true, because when the velocity is doubled, the same quantity of air touches twice the amount of rubbing surface, or meets with twice the number of resisting particles, and strikes each particle with double the force; hence, the resistance offered when the velocity is doubled is $2 \times 2 = 4$ times the original resistance. The unit of resistance is the amount of resistance (lb.) offered by one square foot of rubbing surface to a current having a velocity of one foot per minute. The total resistance is therefore obtained by multiplying the unit resistance (k) by the number of square feet of rubbing

surface (s), and that product by the square of the velocity (v^2). The total resistance, as mentioned above, is equal to the ventilating pressure, or the total pressure upon the airway (pa). Hence, for the total resistance we write $R = pa = ks v^2$.]

Ques. 11.—If the water gauge shows a depression of $\frac{1}{2}$ inch what is the velocity of air per minute when a cubic foot of air weighs .076 pound?

Ans.—The head of air column (h) in feet, corresponding to a given water gauge (i) in inches, calling the weight of one cubic foot of air w , is determined as follows:

$$h = \frac{5.2 \times i}{w} = \frac{5.2 \times \frac{1}{2}}{.076} = 34.21 \text{ ft.}$$

The theoretical velocity due to this head of air column is given by the expression $v = \sqrt{2gh} = \sqrt{2 \times 32.16 \times 34.2} = 46.91$ ft. per sec. This is not, however, the velocity of the airway due to this pressure. The theoretical velocity means simply the velocity due to a certain height, where no resistance is encountered. The actual velocity in the airway due to any pressure, is always less than the theoretical velocity due to the same pressure, and depends upon the resisting power of the airway. [This theoretical velocity is the same velocity as a body will acquire in falling through the height h , in a vacuum. In the circulation of fluids this height h is called the *pressure head*, and the theoretical velocity of the flow (ft. per sec.) is given by the expression $v = \sqrt{2gh}$. The pressure head (in air, head-of-air-column), is always found by dividing the unit pressure, or pressure per unit of area, (p), by the weight of one cubic foot of the flowing medium.]

Ques. 12.—If, at 80 revolutions of the fan, a water gauge of 2 inches and 150,000 cubic feet of air are produced, what would be the water gauge and quantity of air at 50 revolutions?

Ans.—It is customary to assume roughly that the quantity of air in circulation is proportional to the speed of the fan, for any given fan and airway, and the pressure to vary as the square of this speed, which will give as follows: For the quantity, 80 : 50 :: 150,000 : x , or $x = 93,750$ cu. ft. per min.; for the water gauge, $80^2 : 50^2 :: 2 : x$, or $x = \frac{5}{4}$ inch of water gauge.

[In practice, however, this proportion does not hold true, but the quantity varies more accurately as the fifth root of the fourth

power of the speed; or, in this case, as $\sqrt[5]{\left(\frac{5}{8}\right)^4} = .6866$; and $150,000 \times .6866 = 102,990$ cu. ft. per min. In like manner, since the pressure varies as the square of the quantity, it will vary in

this case as $\sqrt[5]{\left(\frac{5}{8}\right)^8} = .4714$; and $2 \times .4714 = .9428$ inches of water gauge.]

Ques. 13.—If it becomes necessary to stop a fan for repairs, how would you keep the mine clear of gas in the meantime? What precaution should be taken before stopping the fan?

Ans.—A steam jet or blower should be arranged at the foot of the upcast shaft, or if this is not sufficient, a temporary furnace may be constructed at the foot of the upcast shaft, taking ample precautions to avoid any risk of fire by making the furnace very small, and protecting the same as much as possible. Or, a fire basket may be hung in the upcast shaft; the basket should be suspended or hung as near to the bottom as possible. If the pumps are in good working order, and a plentiful supply of water is at hand, the ventilating current may be assisted by arranging a fall of water in the downcast shaft. The fall of water should be arranged, as far as possible, on the principle of the trompe, and so as to cover the entire area of the shaft. Advantage should also be taken, at the top of the downcast shaft, to catch all the wind that is blowing at the surface, by the erection of a temporary sail or wind cowl.

In case of accident to the ventilating fan at any mine, or the stoppage of the fan for any cause whatsoever, it would be the duty of the mine foreman to notify the men in the mine, and if necessary, to promptly withdraw all the men from the mine workings. [This is made compulsory by the mine law in the Bituminous districts of Pennsylvania.]

Ques. 14.—If with a water gauge of 2 inches, 150,000 cubic feet of air is circulating, what would be the volume of air with a water gauge of 1.64 inches?

Ans.—The volume of air in circulation varies as the square root of the pressure, or as the square root of the inches of water gauge. Hence, the $\sqrt{2} : \sqrt{1.64} :: 150,000 : x$, and $x = \sqrt{\frac{1.64}{2}} \times 150,000 = 135,828$ cu. ft.

Ques. 15.—An airway 8 ft. $\times$ 12 ft. and 4,000 feet long, has 28,800 cubic feet of air, what is the rubbing surface, pressure and horsepower?

Ans.—The rubbing surface is determined as follows: $s = 2(8+12) \times 4,000 = 160,000$ sq. ft. The pressure per square

$$\text{foot, } p = \frac{k s q^2}{a^3} = \frac{.000000217 \times 160,000 \times 28,800^2}{(8 \times 12)^3} = 3.255 \text{ lb.}$$

$$\text{The horsepower, h. p.} = \frac{28,800 \times 3.255}{33,000} = 2.84 \text{ h. p.}$$

Ques. 16.—What are the essential parts of a safety lamp?

Ans.—The essential parts of a safety lamp are: the oil vessel, the gauze or gauzes, the glass cylinder, the bonnet, the inner chimney of the Meuseler lamp, the various forms of deflectors where used, and the port holes for the entry of air into the lamp, together with the frame or standards that bind the different parts together, and the lock which prevents the untimely opening of the lamp.

Ques. 17.—What are the best precautions against explosions of gas, and fires in mines?

Ans.—The best precaution to be taken against the explosion of gas, and fires resulting therefrom, is the maintaining of an ample air current in circulation in the mine, and causing this current to sweep the entire working face of the mine, also the thorough ventilation of the abandoned portions of a gaseous mine. The daily and regular examination of all the working places of a mine by the fire boss, to ascertain that the air current is passing properly and in sufficient quantity through the airways and working places, and that the timbering is sufficient to prevent falls of roof, whereby large quantities of gas are often liberated. A standard mercurial barometer should also be located at the mouth of every gaseous mine, and the variations of the atmosphere carefully observed each hour of the day. Any sudden change in barometric pressure should be reported at once to the mine foreman, and extra precautions taken to prevent a dangerous increase of the percentage of gas in the air current. Precautions should also be taken against the accidental ignition of gas feeders, from the flame of a blast, which has often given rise to serious fires in mine workings. Gas feeders in the floor often become ignited in this way, and draw back under the gob or waste, and burn for days. These burning feeders should be extinguished as soon as they are detected. This may often be done by the explosion of a small amount of dynamite in the vicinity of the burning gas, the concussion of the explosion extinguishing the flame. Mine fires resulting from spontaneous combustion, in the gob and waste places of a mine, should be particularly guarded against, and every means used to extinguish such fires when discovered. This class of gob fires is best prevented by taking the precaution of loading out the "fines" or coal slack, instead of storing the same in the gob.

Blasting in dusty mines or in gaseous workings should only be allowed after a thorough examination of the working face in the vicinity of a shot. Every shot should also be examined by an authorized person who has the power to condemn and prevent the firing of any shot that, in his opinion, is unsafe. The working face in the vicinity of the blast should always be free from accumulations of gas and fine dust, and where the coal is particularly soft and gaseous the immediate vicinity of the blast should be sprinkled before a shot is fired.

Ques. 18.—Explain the symbols CH_4 , CO_2 , SH_2 , and what are their comparative weights?

Ans.—The symbol CH_4 is the symbol of carburetted hydrogen or marsh gas. Each molecule of this gas consists of one atom of carbon chemically united to 4 atoms of hydrogen. The carbon is represented by the symbol C , and the hydrogen by the symbol H , the number of atoms being indicated by the small subscript letter following the symbol.

The symbol CO_2 stands for carbonic acid gas. Each molecule of this gas consists of one atom of carbon chemically united to two atoms of oxygen; the symbol for oxygen being O . The symbol SH_2 , or as it is more usually written, H_2S , stands for sulphuretted hydrogen gas; each molecule of this gas consists of two atoms of hydrogen chemically united to one atom of sulphur; the symbol of sulphur being S .

The molecular or comparative weights of these gases are as follows: CH_4 , 16; CO_2 , 44; H_2S , 34.

Ques. 19.—Explain the safest and most effective way of circulating air through mines.

Ans.—The safest and most effectual method for the ventilation of mine workings is that in which the main air current is divided into two or more splits, as near as practicable to the bottom of the downcast, each of these splits being employed for the ventilation of separate districts of the mine. These splits, which are known as *primary splits*, should be again divided into other or *secondary splits*, at any point of the mine in which such division can be accomplished to advantage. By this means each district of the mine is provided with its own circulation and receives purer air, inasmuch as the return air from any district in the mine is not conducted around the working face of any other district; but passes directly into the main return airway, and thence to the bottom of the upcast shaft. Any

derangement of the current in one district does not necessarily affect the circulation in other districts of the mine. If for any reason a larger quantity of air than usual is required at any one point in the mine, this can be accomplished readily in this method by reducing the quantity of air in any one or in all of the other splits. This is an unquestioned advantage, especially in the ventilation of gaseous mines, and as we say, the ventilation by this means is more readily controlled.

Ques. 20.—A slope is $4\frac{1}{8}$ inches on the mine map, the tidal elevation of the top is 780 feet, at the bottom of the tidal elevation is 530 feet, what is the length and grade of the slope?

Ans.—Assuming that the mine map is drawn to the usual scale of 100 feet to the inch, 4.6 inches upon the mine map corresponds to a distance of $4.6 \times 100 = 460$ feet. This is the horizontal length of the slope. The rise of the slope is $780 - 530 = 250$ feet. The tangent of the slope angle is $\frac{250}{460} = .54348$; and the angle of the inclination of the slope is therefore $28^\circ 31'$; the grade of the slope is 1 : 1.84, or one foot of rise in 1.84 feet horizontal distance, or 5.43 per cent.

$$\text{The length of the slope is } \frac{460}{\cos. 28^\circ 31'} = \frac{460}{.8787} = 523.5 \text{ ft.}$$

Ques. 21.—A breast is 400 feet long, on map it is 3.76 inches, what is the vertical height at face from level of gangway?

Ans.—Assuming, as in the last example, the scale of the map to be 100 feet to the inch, the horizontal length of the breast would be $3.76 \times 100 = 376$ feet. The length measured upon the pitch being 400 feet, the vertical height or the rise at the face of the breast would be $\sqrt{400^2 - 376^2} = 136.5$ feet. Or, we may first find the pitch angle thus, $\frac{376}{400} = .94$ is the cosine of the pitch angle. Hence, the angle $= 19^\circ 57'$. Then, $400 \times \sin 19^\circ 57' = 400 \times .3412 = 136.48$ feet, length of breast measured on the pitch.

Ques. 22.—The gangway is driven N 50° E, the breasts N 10° W, the pillars are 30 feet wide, and breasts are 24 feet wide, what is the distance between center line of breasts on the gangway?

Ans.—The angle between the gangway and the breast is found in this case by adding the angles of the respective bearings of the gangway and breast. Thus, $10^\circ + 50^\circ = 60^\circ$. Then $\frac{30 + 24}{\sin 60^\circ} = \frac{54}{.866} = 62.36$ feet, distance between center lines of breasts measured on the gangway.

Ques. 23.—Describe the conditions requiring that a mine be worked by locked safety lamps, and what provisions should be made to have extinguished lamps relighted.

Ans.—Locked safety lamps should be employed in any mine generating or known to have generated explosive gas, in order to ensure absolute security against explosion. This requirement, however, is not put into practice as stringently as safety would often require. Many mines while generating explosive gas yield this gas in such small quantities and so regularly as not to present the dangerous conditions that would demand the use of locked safety lamps. Other mines generate larger quantities of explosive gas for a given time, after which the quantity of gas given off at the face decreases and the use of locked safety lamps is often abandoned, in such cases. Still other mines in the immediate neighborhood of gaseous workings give off but little gas, and seem not to require the continuous use of safety lamps. All of these mines present conditions that would demand the use of locked safety lamps in order to guarantee absolute security against explosion, but inasmuch as the use of the safety lamp is to an extent a hindrance to his work, the miner is prone to expose himself to considerable risk in this regard; and very much prefers to use a naked light, except where the conditions are manifestly present demanding the use of safety lamps only.

Rule 9, Art. 12, of the Anthracite Mine Law of Pennsylvania reads as follows:

"In every working approaching any place where there is likely to be an accumulation of explosive gases, or in any working in which danger is imminent from explosive gases, no light or fire other than a locked safety lamp shall be allowed or used."

The law therefore requires the use of locked safety lamps in workings approaching abandoned workings, as gas may be suspected, or in workings where dangerous accumulations of gas are liable to occur.

A lamp station should be located upon the intake airway at a point as far inbye as practicable, and free from any danger from explosive gases. This lamp station should be in charge of a duly authorized person who should examine and relight any lamp brought to him for that purpose. Where such a lamp station is not maintained in the mine, all lamps which are extinguished by accident should be sent to the surface for relighting, unless the lamp contains an internal relighter.

Ques. 24.—Describe the best method for hauling coal, by mules, out of a gangway 5,000 feet long, and best grade for the track.

Ans.—The best method for haulage by mules, in such a case, would be to provide partings or turn-outs at suitable distances along the haulage road. This distance for a regular output of say from 500 to 800 tons per day, may vary from 200 to 300 yards in length. One or two drivers may be employed upon each stretch, or between each of the consecutive partings. Two drivers are preferable since they can assist each other in case of difficulty from the derailment of cars, etc., and where the grades are suitable they should follow each other instead of alternating trips. Where there are steep grades upon the haulage road, however, the second driver should not follow the first too closely.

The best grade for the haulage road would be a slight grade in favor of the loaded cars. This grade should not exceed say 3%, a 2% grade being preferable.

Ques. 25.—What kind of haulage would you recommend in place of mules, and why?

Ans.—Mule haulage should be replaced by rope haulage, or motor haulage by compressed air, electric or gasoline motors, as early as the development of the mine admits, for the reason that excepting for very small mines rope or motor haulage is cheaper and much more efficient than mules. Neither do they vitiate the mine air as do mules. [The comparative advantages and disadvantages of compressed air and electricity are enumerated in answer to Ques. 567, Page 457, MINES AND MINERALS, May, 1900. See also, answer to Ques. 27, Page 472, May, 1900; and article, Haulage, page 520, June 1900.]

Ques. 26.—What conditions are required for the successful operation of a siphon?

Ans.—The conditions required for the successful operation of a siphon may be stated as follows:

(1) The height of the summit of the siphon above the surface of the water in the upper basin, or the vertical lift of the siphon, must not exceed a practical limit to which the atmosphere will force the water. This height theoretically is 34 feet, at sea level, and decreases as we ascend above the level of the sea. A safe rule to apply in determining the vertical height to which the atmosphere will force the water in the suction pipe of a pump, or in the short leg of a siphon, is to take .8 of the barometric height, in inches, for the vertical lift of the pump or siphon, in feet. Thus, if the barometer stands at 30", the lift of the pump or siphon may be taken as $30 \times .8 = 24$ feet. Where the suction pipe is nearly vertical, and consequently of shorter length, this height may be somewhat increased; but where the suction pipe is inclined and its length therefore considerable, the vertical lift should be decreased proportionately. [See also answer to Ques. 20, Page 188, MINES AND MINERALS, November, 1899; also article "Can a Siphon Have Too Much Fall" page 474, May, 1900.]

(2) The longer leg, or the discharge pipe of the siphon, must fall through a greater vertical height than the short leg or draft pipe. In Fig. 2, the vertical height h is called the lift,

and the vertical height h_1 , the fall of the siphon. The difference between these heights ($h_1 - h$) may be called the siphon head. When the fall of the siphon (h_1) exceeds the practical limit to which the atmosphere will force the water, care must be taken to arrange the fall of the siphon relative to its lift, according to

the equation $h_1 = \frac{1}{l}(34 - h) + 34$. If this is not done there is a tendency to the formation of a vacuum, at the crown of the siphon, that will cut off entirely, or reduce the flow of water in the siphon. In this case, it is often remarked that the pipe does not run full, and in many instances the flow will cease entirely after a short time. [See also Page 475, MINES AND MINERALS, May, 1900.]

Another important condition requisite to the successful operation of a siphon, is the submerging of both ends of the siphon pipe in their respective basins, in order to prevent air being drawn into the pipe, and reaching the crown or summit of the siphon. This takes place more readily in the short leg of the siphon than it does in the long leg, due to the direction of the flow of the water. The submergence of the discharge end of the siphon, however, is important in order to ensure a full flow in the pipe. Air which is carried into a siphon by the water will gradually

accumulate at the highest point of the siphon pipe and will interfere with the working unless a cock is provided at that point through which the air can be let off from time to time.

Ques. 27.—What maximum height should there be between a pump and the water in the sump, barometer being 30 inches?

Ans.—The rule given in the answer to the preceding question should be applied in this case. Thus, $30 \times .8 = 24$ ft. As explained previously, this height may be increased or decreased slightly, according to the position of the suction pipe and its length. The perfectness of the pump also determines to a certain extent the height which the pump will draw. With the most perfect pump and a short vertical lift, this height will rarely exceed or even equal 28 feet, when the barometric height is 30 inches.

Roadways in Inclined Seams.

In laying out the roadways for haulage in inclined seams, advantage should always be taken of the force of gravity. The road should be given such a bearing with respect to the strike of the seam, as to furnish a slight grade in favor of the loaded cars. This will very much facilitate the movement of the loads, and decrease the expense of haulage. It is an important consideration in the economical operation of a coal seam, since whatever decreases the expense of handling the coal from the face to the tipples increases to that amount the value of the coal on the track.

A few words of explanation in regard to the dip and strike of a seam, will render the situation more clear. The term "strike," as applied to inclined seams, refers to the direction of a level line in the seam, while the term "dip of the seam" refers to the angle the plane of the seam makes with a horizontal plane. The strike of an inclined seam is thus determined by the intersection of that seam with a horizontal plane. This line of intersection will be level, since it lies in a horizontal plane; and it will be a line of strike since it is a level line in the seam. Lay a book upon the table (See figure) and partially raise one cover, so that the raised cover represents an inclined seam. The upper edge of the raised cover ab , or its lower edge cd , is parallel to the plane of the table, and both of these edges are therefore level lines. They both represent lines of strike, since they are level lines in the seam as does also the line NS in which the plane of the raised cover if extended would intersect the horizontal plane of the table. The inclined edges ac and bd , of the raised cover, in like manner represent lines of true dip, or the full dip of the seam. The angle DSH at which the cover is raised, which is the angle that the seam makes with the plane of the table, is the angle of inclination or the dip angle of the seam. This angle is often spoken of as the amount of dip of the seam; or, the amount of dip is sometimes given by stating the rise in any given horizontal distance. Thus, we may say a seam has a dip of 1 in 10, meaning that the line of true dip of this seam rises or falls one foot in every ten feet of horizontal distance. The tangent of the angle of inclination of the seam, in such case would be $\frac{1}{10} = .1$, and the angle of inclination is therefore $5^\circ 43'$ (see a table of natural tangents and cotangents).

When we speak of the bearing or direction of the strike, or of the dip of a seam, we mean the direction either of these lines may have upon the mine map with respect to the meridian, or the angle each makes with the meridian. These angles are obtained by surveying and are always horizontal angles; that is to say, they lie in a horizontal plane. When the bearing of a line is measured with an instrument in surveying, the angle is measured in the horizontal plane. If we project the inclined edge bd of the raised book cover representing the dip of the seam, upon the plane of the table, the projection, or the line SH , will indicate the direction or bearing of the dip of the seam. This direction of dip will thus be represented by the edge oe of the lower cover of the book as it lies upon the table. The angle this projected line makes with the meridian is the bearing or the direction of the true dip of the seam. It must also be remembered that while these angles of direction, or angles denoting the bearing of a strike or dip are horizontal angles, the angle of inclination of the seam is a vertical angle, and is measured in the vertical plane. This angle of inclination DSH is the angle the line of true dip makes with its projection upon the horizontal plane.

Referring to this illustration of the book lying upon the table, with its raised cover representing the plane of the seam, if a slope is driven upon the full dip of this seam, or a heading driven to the full rise of the seam, either of the inclined edges ac or bd of the book, will represent such slope or heading. Any other inclined line in this seam will represent a slant road. Thus, suppose we wish to drive a slope to the full dip of this seam. We will represent this slope by the right-hand inclined edge bd of the raised cover of the book; the upper edge ab and the lower edge cd of the book, being level lines, represent strike lines in this seam, and therefore represent levels or gangways driven upon the strike in the seam. Now, suppose from the lower right hand

corner d of the book we draw upon the raised cover any diagonal line as dx ; this line will represent a slant road in the seam. Extend this line x to intersect the plane of the table at z ; project the point x upon the same plane by a perpendicular xy and draw zy , which will be the projection of xz upon the horizontal plane of the table. The projection yz upon the horizontal plane gives the direction or bearing of the slant road xd , and the angle Nzy between this projected line and the strike line is the angle the

slant road makes with the strike of the seam. This angle is often spoken of as the angle between the slant road and the level or gangway. It is not the angle cdx or Nzx in the seam, but its projection Nzy upon the horizontal plane. The dip of the slant road, or its grade or angle of inclination, xzy will vary from zero, to an angle equal to the true dip angle, or angle of inclination of the seam. The grade of the slant road will be less as its direction approaches the direction of the gangway, and greater as its direction approaches the direction of the true dip of the seam. In the figure the strike of the seam is due north and south, and the maximum or true dip is due west.

A simple rule for determining the grade of a slant road in a seam of any inclination, when the slant road makes a given angle Nzy , with the level or strike of the seam, is as follows: The percentage of grade of the slant road is equal to the product of the sine of the angle the road makes with the strike of the seam, and 100 times the tangent of the angle of inclination of the seam. Thus, calling the angle of inclination of the seam α , and the angle the road makes with the strike of the seam θ , we have,

Percentage of grade of slant road = $100 \times \tan \alpha \times \sin \theta$, 1.
Or, if the grade of the slant road is given by its dip angle, or angle of inclination, and calling this angle β , we have,

$$\sin \theta = \frac{\tan \beta}{\tan \alpha}, \quad 2.$$

The formulas just given enable us to determine very quickly the percentage of grade of any slant road, in a seam of a given inclination; or to determine the angle that a slant road must make with the strike of a seam of a given inclination, in order to have any given rise or dip (grade).

It is to be observed that it is always possible from a given point of a level or gangway, in any inclined seam, to drive two slant roads to the rise, or two slant roads to the dip, each having the same grade. One of these two roads will be driven to the right and the other to the left of the true pitch or true dip of the seam; but each of them will make the same angle with the strike of the seam or the level or gangway.

Example.—To illustrate the use of these simple formulas, suppose it is desired to ascertain the bearing of a northwesterly slant road having a 5 per cent. grade, in a seam whose inclination is 20° , the direction of the dip of the seam being $N 4^\circ 30' W$.

Solution.—The true dip of the seam being $N 4^\circ 30' W$, the line of strike, or the line at right angles to this will be $S 85^\circ 30' W$. To find the angle that a slant road having the required grade, makes with the strike of this seam, we have,

$$\sin \theta = \frac{\tan \beta}{\tan \alpha} = \frac{.05}{\tan 20^\circ} = \frac{.05}{.364} = .13736;$$

which makes the required angle between the strike line and the

slant road $7^\circ 54'$. Hence, since the slant road is to be a northwesterly road, its bearing will be $180^\circ - (85^\circ 30' + 7^\circ 54') = 86^\circ 36'$; or bearing is $N 86^\circ 36' W$.

Example.—Suppose it is required to determine the percentage of grade of a slope or heading in this seam (inclination of seam 20° , direction of dip $N 4^\circ 30' W$), the bearing of the slope being $N 10^\circ 15' E$.

Solution.—As before the direction of strike of this seam is $S 85^\circ 30' W$, or for this case, say $N 85^\circ 30' E$. The angle that the slope makes with the direction of slope will then be $85^\circ 30' - 10^\circ 15' = 75^\circ 15'$. We have then for the percentage of grade, $100 \tan \alpha \times \sin \theta = 100 \times .364 \times \sin 75^\circ 15' = 36.4 \times .967 = 35.2$ per cent. This grade corresponds to a rise of 35.2 feet in 100 feet of horizontal distance. The angle of inclination of the slope is therefore the angle whose tangent is .352; or the angle of inclination of the slope is $19^\circ 23' 30''$.

Particular attention is called to the fact above mentioned that the bearings of lines and roadways, are the angles which the projection of these lines or roadways, upon a horizontal plane, make with a meridian line. These bearings are always measured in the horizontal plane and are therefore, horizontal angles. Angles of inclination on the other hand, are measured in a vertical plane, and are therefore vertical angles. An angle measured with an instrument is never measured in an inclined plane; the planes of the instruments must be either horizontal or vertical. For this reason, when we speak of the angle a road makes with the true dip of the seam, we mean the horizontal angle between the projection of that road upon the horizontal plane, and the projection of the true dip upon the same plane. We do not mean the angle between the roadway and the line of dip, in the seam.

Size and Shape of Airways.

The question is often asked, what is the best form and size for an airway in mine ventilation. This is an important question and calls for careful consideration, which can only be given after an intelligent understanding of the theory of conducting air currents through airways as well as a thorough experience in practical mining. When we speak of the best form and size of airways in mining, we mean that form and size of airway that will produce the best economic results with respect to the ventilation of a mine. The question is affected by considerations (1) of a theoretical nature, and (2) of a wholly practical nature. From a theoretical standpoint the best form of airway is that which will circulate the largest quantity of air with the same expenditure of power.

Power Producing Ventilation.—The simplest expression for the power producing ventilation is

$$u = k s v^3, \quad 1.$$

where u = work performed per minute (foot-pounds),

k = unit of resistance offered by one square foot of rubbing surface to a current having a velocity of one foot per minute (lb.),

s = rubbing surface of the airway (sq. ft.),

v = velocity of the air current (ft. per min.).

Writing this expression for the work performed per minute, $u = (k s v^3) \times v$, and remembering that $k s v^3$ is the expression for the resistance of the airway, we see that the above equation expresses the work necessary to produce a given velocity against a given resistance.

Substituting in equation 1 for s its value $l o$, and for v its value $\frac{q}{a}$ we obtain

$$u = \frac{k l o q^3}{a^3}, \quad 2.$$

where l = length of airway (ft.),

o = perimeter of airway (ft.),

q = quantity of air in circulation (cu. ft. per min.),

a = sectional area of airway (sq. ft.).

Equation 2 expresses the work performed in circulating a given quantity of air in a given airway, and is the equation we

FIG. 1.

must use in determining what form of airway will yield the largest quantity of air, with the same expenditure of power.

Form of Airway That Will Circulate the Largest Quantity of Air With the Same Power.—The three typical forms of airway are shown in Fig. 1. These are the circular, square and rectangular forms.

The dimensions given, in the figure, for each airway are such as to make the areas equal. Referring to equation 2, we observe that for any given power the quantity of air circulating in airways of the same length and having the same sectional area, varies inversely as the cube root of the perimeter, or q varies inversely as $\sqrt[3]{o}$. Now, comparing the several forms of airways having equal areas, and expressing the perimeter of each of these forms in terms of the area, we have

$$\text{Circular airway; } o = 3.1416 \sqrt{\frac{a}{.7854}} = 3.5449 \sqrt{a}.$$

$$\text{Square airway; } o = 4\sqrt{a}.$$

$$\text{Rectangular airway; (calling shorter side } d, \text{ and longer side } r d, r \text{ being any ratio greater than 1), since } a = d \times r d = r d^2, d = \sqrt{\frac{a}{r}}, \text{ and } o = 2(d + r d) = 2\sqrt{r} \left(\frac{1}{r} + 1 \right) \sqrt{a}.$$

The relative perimeters and quantities are therefore as follows:
Circular airway, rel. perim. 3.5449;

$$\text{rel. quant. } \frac{1}{\sqrt[3]{3.5449}} = .6558 \text{ cu. ft.}$$

$$\text{Square airway, rel. perim. 4; rel. quant. } \frac{1}{\sqrt[3]{4}} = .63.$$

$$\text{Rectangular airway, rel. perim. } 2\sqrt{r} \left(\frac{1}{r} + 1 \right);$$

$$\text{rel. quant. } \frac{1}{\sqrt[3]{2\sqrt{r} \left(\frac{1}{r} + 1 \right)}},$$

or calling the quantity of air circulating in a circular airway of a given sectional area, with the expenditure of a given power, unity or 1, the quantity circulating in a square airway of the same area and length, with the same expenditure of power, would be .9605; and the quantity circulating in a rectangular airway whose width is twice its height ($r = 2$), the airway having the same area and length, and the power being the same, would be .9419. That is to say, for every 10,000 cubic feet of air a given power will circulate in a circular airway, the same power will circulate 9,605 cubic feet in a square airway of the same length and area; or 9,419 cubic feet in a rectangular airway of the same length and area, when the width of the airway is twice its height ($r = 2$). These comparative quantities will be of value as showing the effect of the form of the airway upon the circulation due to any given power.

Size of Airway Affects Velocity of Current.—The size of an airway is also an important consideration. This is determined by the volume of air which the airway is required to pass, since if the sectional area of the airway is too contracted for the quantity of air in circulation, the velocity resulting in the airway will be too high; and on the other hand, if the sectional area of the airway is too great the resulting velocity of the air current will be too low. The velocity in practical mine ventilation should be maintained between certain limits. If the velocity is too low, the air current does not fulfill its purpose, which is to sweep the gases from the cavities of the roof and sides of the airway where they accumulate. If the velocity is too high, it results in discomfort and annoyance to the men working upon the airway, and in gaseous mines there is danger of the flame of the safety lamp being blown through the gauze. For these reasons the practical limits of the velocity of the air current for gaseous mines is, say from 240 to 450 lineal feet per minute. In non-gaseous mines these limits may be extended from 180 to say 1,200 or 1,500 lineal feet per minute. The Anthracite Mine Law of Pennsylvania limits the velocity of the air current in mines generating explosive gases to 450 lineal feet per minute.

The same rule should be applied in ascertaining the proper size of an air shaft. The sectional area of the shaft should be estimated from the quantity of air which it is desired to circulate, but a higher velocity may be used in estimating the size of a shaft. The velocity in the shaft will at times reach as high as 3,000 lineal feet per minute.

Practical Considerations.—Aside from theoretical considerations, the form of airways is modified and largely determined by practical conditions. As we have just seen, from a theoretical point of view the circular airway is the form that presents the best conditions for economical ventilation. In practice this form of airway is rarely adopted in American mines, except in some instances where entry driving has been performed with the Stanley header. Where this machine is used in entry driving, the sectional area of the airway is a complete circle, and if the machine is followed closely with the work of lining the airway with a cylindrical lining, the circular form may be retained in the finished airway. The expense of making this form of airway secure, however, prevents its common use. A more usual form of airway is one having a semi-circular arch for a roof, the sides and

floor of the airway being cut square. This form is very common in tunnel work.

The two remaining forms of airway, the square and the rectangular airway, present conditions which are readily attained in ordinary mine work. In thick seams, airways having a cross-section which approaches more or less closely to a square are very common, while rectangular airways, having a width considerably greater than their height, are most common in thin seams. The reason for this is obvious, since the expense of brushing the roof or lifting bottom to increase the height of an airway over that afforded by the thickness of the seam is expensive, and is only resorted to in the construction of passageways where it is an absolute necessity to obtain sufficient height for mules and men. In thin seams it is usually considered an unwarranted expense to make the height of an airway greater than the thickness of the seam, except only where there is a draw slate or similar stratum, overlying the coal, that falls after the coal has been extracted. In such cases the timbering of the airway is delayed for a season until the roof stratum or draw slate has fallen, when the airway is cleaned up and timbered.

It is important to know the theoretical conditions that affect the form of airway, and to know which form produces the best economical results, in order that we may profit by such knowledge, in the adoption of such form of airway when the practical conditions will permit. These practical conditions always control the actual work of mining.

Another common form of airway is that of the trapezoid. We have not considered this form however, inasmuch as its consideration does not differ from that of rectangular airways. In any of these forms of airway the quantity of air, for the same power, and for the same length and area of airway, will vary inversely as the cube root of the perimeter. The trapezoidal form of airway will always present a slightly greater perimeter, for the same sectional area, than a rectangular form of airway; and the quantity of air passing in the former will therefore be slightly less than that passing in the latter, for the same power. The difference, however, between these two forms of airways is very small and need not be considered separately as a class.

How to Make Gold Dredging Pay.

Many men whose opinions are trustworthy on other subjects are entirely unable to form a sane or just conclusion on matters connected with gold. Many, if not most, men also are inclined to put a better face on the question than usually exists, and the sight of a few yellow colors leads them at once to figure out a bonanza. If investors would only bring to bear on gold mining the same prudence and business sense which is necessary in any other business, it would greatly reduce the number of failures. The investor has to guard against two classes of evil advice. One is that of the professional swindler who "promotes" the property for the sole purpose of transmitting the funds of the subscribers into his own pocket, and the other is the well-meaning man who perhaps has a fairly good thing if properly worked, but who has more self-confidence than experience and skill.

The ground should be surveyed,—if not accurately at least approximately—and a map prepared on which may be recorded the positions of the test-pits, the area available, and the extent of the ground worked over each season. Test-pits should be sunk at sufficiently frequent intervals to place the nature of the ground beyond conjecture. The examination should show the full depth of the gravel, the nature of the bedrock, if any, and the distribution of the values; whether they are greatest at the surface, in layers, or on the bottom. Values are never uniformly distributed, and nothing is more deceptive than a glib statement of so much per cubic yard.

The nature of the material should also be ascertained, and this not only on the surface. The sizes and percentages of the gravel, from coarsest to finest, should be measured. This is necessary to determine the character of screens to be used, or whether any at all are necessary. The action of the gravel while being washed or sluiced should be experimentally determined. Some gravels wash very freely; others, again, are of a clayey or sticky nature which renders them very difficult to wash. Other deposits are of a very hard or cemented nature, often with large boulders, which increase the difficulty of working. The condition of water supply is most important. Water is essential to the recovery of gold, and its presence in suitable quantities is a great desideratum.

The disposition of tailings is a subject which must be carefully studied. Unless the dredge can get rid of all material passed through without choking or piling up in such a manner as to interrupt its work, it is liable to be stopped, and the entire enterprise brought to a standstill until the difficulty can be remedied. The configuration of the ground, the character of the material, the depth of the water, and the height of ground worked above water,

all enter into the question and should be carefully determined. As to the gold itself, the question is threefold. There are to be considered, first, the character of the gold; second, its value per cubic yard of material handled; third, the best method of saving it. On the satisfactory determination of these points the whole success of the enterprise depends, and here long experience and sound judgment are absolutely necessary. The gold may be fine or coarse, of all degrees, and may be easy to save or difficult to save, and the most effective method of saving it depends upon its character. There is no "new discovery" for gold saving. All known methods depend on one thing for their successful action, namely, the great specific gravity of the gold as compared with gravel. Their separation can be effected only by washing with water, aided sometimes by amalgamation, but the methods of washing are subject to wide variation.—A. W. Robinson in *Cassier's Magazine* for October.

Coal Mined by Machines in 1899.*

The increase in the use of undercutting machines in the bituminous coal mines of the United States continues to be one of the most interesting features of the industry. The statistics relating to the machine-mined tonnage have been collected for 1899 as for the three preceding years, and results are presented in the accompanying table. The statement shows that the amount of coal produced by machines in 1899 was 43,963,933 short tons, an increase as compared with 1898, of 11,550,789 tons. The increase in 1898 over 1897 was 9,763,924 short tons, while the increase from 1896 to 1897 was 6,224,288 short tons. In collecting the statistics of machine mining for 1896 the inquiries were made to cover also the year 1891. The results obtained show that in 1891 the total product by machines was 6,211,732 short tons, nearly half of which was in Illinois, while Ohio made up another fourth. In 1896 the machine-mined product had increased to 16,424,932, a gain in five years of more than a million tons less than the gain each year from 1897 to 1899.

There were 22 States and Territories in which machines were used in 1899. Two States and one Territory in which a machine-mined tonnage was reported in one or more of the preceding years did not report any machines used in 1899. These were Alaska, Texas, and Utah. Maryland introduced machines for the first time in 1899, two companies installing a total of 8 air-driven pick machines, and having a product from them of 16,545 short tons. Washington, which did not report any machines in use in 1897 and 1898, is added again to the list of States using machines in 1899. The total number of States having machines in use last year was 22, against 21 in 1898, 20 in 1897, and 16 in 1896. The number of firms employing machines has increased from 136 in 1896 to 335 in 1899, while the number of machines in use has increased in the same time from 1,446 to 3,125. In the same period the total bituminous coal product of the United States has increased from 137,640,276 short tons to 193,321,987 short tons, a gain of 55,681,711 tons, or 40 per cent. The total product in the States having machines in use has increased from 115,921,828 short tons to 191,144,218 short tons, a gain of 75,222,390 tons, or 65 per cent., while the machine-mined product has increased from 16,424,932 short tons to 43,963,933 short tons, a gain of 27,539,102 tons, or 168 per cent.

Considering the statistics by States, it is seen that there were 4 States in which the machine-won product in 1899 was less than in 1898. These States were Alabama, Arkansas, Iowa, and North Dakota. Satisfactory explanation for this decrease is not given except in Arkansas, where some of the large mines using machines were idle because of strikes a good part of the year. New Mexico reported a decrease from 29 to 15 in the number of machines in use, but a substantial increase in the tonnage. Pennsylvania is credited with the largest increase, 258 machines and 5,488,242 tons being added to the figures for 1898. Illinois comes second in the increase of tonnage, adding 2,669,677 tons to the machined product of 1898. Prior to 1899, the amount of coal won by machines in Illinois had not reached 4,000,000 tons in any one year. In 1899 it exceeded 6,000,000 tons. This remarkable increase in 1899 is explained in part by the fact that a large number of machines reported in 1898 were not introduced until late in that year, and their influence on the tonnage was not apparent. Further explanation is found in the strikes which paralyzed the coal-mining industry of Illinois in 1898, causing a decrease of nearly 1,500,000 tons in the total product, and affect-

ing particularly some of the mines in which machines were used. There was a decrease of over 500,000 tons in the machine-mined product of Illinois in 1898 as compared with the preceding year. West Virginia was next to Pennsylvania in the number of machines added in 1899. There was a gain of 68 machines in West Virginia in 1899 as compared with 1898, but as some of these were not installed until late in the year the tonnage did not increase in proportion. There was, however, an increase of over 550,000 tons in the machine-mined product. Ohio added 33 machines to the number reported in 1898 and 1,631,149 tons to the product won by them. Colorado increased the number of machines in use from 43 to 63, and added over 300,000 tons, or about 133 per cent, to the machine tonnage. In this State, as in Illinois, the product in 1898 was reduced by strikes. The changes made in the other States were unimportant.

The coal mined by machines in 1899 constituted 23.00 per cent of the total product as compared with 20.39 per cent in 1898, 16.19 per cent in 1897, and 14.17 per cent in 1896.

In the following table is exhibited a detailed statement of the number of machines of each make in use in the bituminous coal mines of the United States in 1899. The pick or "punching" machines exceed in number, there being 1,997 out of a total of 3,125. Of the remainder, 1,106 were chain breast machines and 22 longwall. The latter are used only in the States west

of the Mississippi River—Arkansas, Iowa, Kansas, and Missouri. The pick machines include 992 Harrison, 317 Sullivan, 590 Ingersoll-Sergeant, and 98 "other" makes, or of which the make was not reported. The chain machines include 114 Jeffrey air, 450 Jeffrey electric, 401 Morgan-Gardner electric, 95 Independent or Link-Belt electric, 15 Morgan-Standard electric, and 31 other.

What is Seigniorage?

This term, as used in the United States, means the profit arising from the coinage of bullion. The Government does not purchase gold bullion, but coins it on private account. There is no profit from the coinage of gold bullion, the face value of gold coins being the same as their bullion value, but at the present ratio of 16 to 1 the face value of the silver dollar is greater than its bullion value; therefore when silver bullion is purchased and coined into dollars there is a profit arising from such coinage, the amount of which depends upon the price paid for the bullion. For example, there are 271½ grains of pure silver in a dollar and there are 480 grains of pure silver in a fine ounce. The coinage value of a fine ounce is therefore \$1.2929. If the fine ounce can be purchased for 70 cents, the profit of its coinage (the seigniorage) is \$0.5929—, and the profit on the 371½ grains of pure silver in the single dollar is \$0.4586—, which is the difference between the actual cost of the bullion in the dollar and the nominal value of the coin. The silver purchased by the Government is carried on the books of the Treasury at its actual cost, and the seigniorage is declared on the coinage of each month and paid into the Treasury.

*Extract from the "Production of Coal in 1899," by E. W. Parker, U. S. Geological Survey, Washington, D. C.

COMPRESSED AIR LOCOMOTIVE.

Some of the Reasons Why They Are Often Preferred in Mines. Principles Governing Their Construction.

Written for MINES AND MINERALS, by H. K. Myers, C. E.

Locomotive haulage in mines has for many years proven very efficient where conditions were favorable. When the grades do not exceed for short distances 5% and an average of 3% maximum against the loads, or for short distances 8% and average of 5% maximum in favor of loads, it has been found in general that it is the most economical form of haulage.

The chief advantages of locomotive over rope haulage are the flexibility of the system, it being able to serve any number of side tracks in various parts of the mine, and the closeness of the source of power to the point of application. In the event of an accident due to a car jumping the track, a broken wheel, etc., it often happens that a large number of cars are piled up before the man in charge outside the mine is signaled to stop, whereas with locomotive haulage the engineer or trip rider affords immediate relief.

Where the seam of mineral is high and the location such that there is neither inflammable gases nor danger of vitiating the air, steam locomotives are found very economical as has been specially proven in the Pocahontas coal field of West Virginia. Even there, with their high seams, it has been determined that there is a limit to this form of haulage. It is not found feasible to fire while running in the mine, especially when bituminous coal is used, hence the length of the trip underground is limited to the

storage at least double that of the locomotives comprising the system. This allows an equalized pressure in the locomotive storage of approximately 600 lb.

The following formula is useful in determining the capacity of stationary storage: V = volume of storage on locomotive; X = volume of stationary storage desired; p = cylinder pressure; P = stationary storage pressure; and P' = locomotive storage pressure.

Now, since it is considered good practice to use the air from the locomotive storage until it has been reduced to the cylinder pressure, we would have it applying for a charge when it contained a pressure of p . Then $\frac{pV + PX}{V + X} = P'$, that is, the

product of the storage on the locomotive by its pressure added to the product of the stationary storage by its pressure and the sum divided by the combined volumes will give the equalized pressure or the final pressure in the locomotive storage.

If the average time for each trip is 30 minutes, the compressor must be able to compress in that time to pressure P the calculated amount of air required for one trip or series of trips for the various locomotives included in the haulage. In general, it is customary to extend extra strong pipe into the mine and of such length and diameter as to have the required volume for the stationary storage. There are times however when it would be found more economical to arrange for tank storage either inside or outside the mine but in general, especially when the mine is advancing, it is the better practice to install pipe storage since it increases the range of the locomotive as the workings advance.

Table No. 1 gives the various tractive efforts of different sizes

A 60,000 LB. MINE LOCOMOTIVE.

steam furnished with one fire-box of fuel. It is customary to fill the fire-box, and, after the greater part of the darker colored gases have passed off, to take the empty trip into the mines returning with the loaded cars, all with the one fire-box of coal. Possibly the largest locomotive ever constructed for mine haulage is the one shown in the accompanying figure. It was built for the Southwest Virginia Improvement Co., Pocahontas, W. Va., and weighs 60,000 lbs. with everything in proportion. This locomotive is able to make a round trip of seven miles without firing and on account of the dimensions is possibly the maximum for steam mine locomotives.

To overcome the many difficulties and dangers incident to the use of steam locomotives underground, a large variety of both compressed air and electric locomotives have been designed in recent years and in general they have been very successful and show a marked efficiency over the mule.

In order that compressed-air locomotives may be able to make a fair length of run, the tanks for storage purposes must necessarily be rather cumbersome, and constructed to carry high-storage pressures. In order that they may be designed correctly and get a minimum of storage for the maximum work expected, it is necessary to have a complete profile of the proposed haulage, and to make a tabulated statement of the air consumption on the various grades, noting the "cut-off" necessary to produce the requisite tractive effort. By making a summation of these various amounts, and adding 20%, we will have the possible amount of air used in doing certain work as specified.

It is necessary, therefore, to provide storage on the locomotive for this amount of air at a much greater pressure than that used in the cylinders. In order that the locomotive may receive a quick charge at the stations specially provided for the purpose, it is necessary to have the stationary storage of adequate pressure and capacity for the purpose.

At the present time, it is the custom to compress for the stationary storage to 800 lb., and to have the volume of this

of compressed-air locomotives, when working at 100 lb. cylinder pressure, and various cut-offs. If other pressures or strokes are used, the tractive efforts are directly proportionate. This table is calculated by means of the formula,

$$\text{tractive effort} = \frac{d \times l \times x p}{D}$$

in which d = diameter of cylinder; D = diameter of driver; l = length of cylinder or stroke; p = working pressure of the cylinders; and x = variable due to the various cut-offs.

TABLE NO. 1.

TRACTION EFFORTS OF COMPRESSED-AIR LOCOMOTIVES.

Cylinder.		Diameter of Driver. Inches.	Weight on Driver. Pounds.	Tractive Effort for Each 100 lb. Cylinder Pressure at Various Cut-Offs.						
Diam. Inches.	Stroke. Inches.			1"	2"	3"	4"	5"	6"	7"
5	10	24	6,000	1,020	990	920	835	710	530	325
6	10	24	8,500	1,470	1,425	1,320	1,200	1,020	760	445
7	12	26	13,000	2,200	2,150	1,990	1,810	1,540	1,140	700
8	12	26	18,000	2,890	2,760	2,600	2,360	2,000	1,510	900
9	14	26	25,000	4,340	4,140	3,840	3,490	2,960	2,220	1,350
10	14	26	32,000	5,280	5,150	4,740	4,310	3,660	2,630	1,670
11	16	28	42,000	6,770	6,450	5,980	5,440	4,620	3,470	2,440
12	16	28	52,000	8,050	7,800	7,200	6,560	5,580	4,150	2,850

On account of certain losses due to radiation, etc., for cut-off at full length of stroke in steam practice x is taken as .85. While cylinder surface acts as a detriment to the use of steam, it acts entirely opposite in the use of air, for the reason that, in the expansion of the air, very low temperatures are produced, and, with a maximum of cylinder surface exposed, we absorb a maximum of heat from the surrounding air, which virtually adds new energy to the air, thus acting as a reheater. Therefore, in air

practice, this factor x is made .95 for full-stroke cut-off, with the others proportionately high. If simple-expansion cylinders are used, the working pressure should not exceed 130 lb., while, with compounds, one can easily use from 180 to 225 lb. with great economy.

Where it is imperative to have a minimum-sized locomotive storage with a maximum run, this can be accomplished with compound locomotives, since by using the air at high pressures advantage is taken of the energy developed by the expansion of the air from the higher to the lower working pressure. If we have two locomotives, one working at 200 lb. and the other at 130 lb., the former should have an efficiency over the latter, simply due to the working pressure, of an amount equal to the power necessary to compress the air used from 130 lb. to 200 lb. If both locomotives were simple cylinders and of same diameter, it is possible that the higher pressure would prove the more inefficient for the reason that the exhaust pressure would be very high and the leakage very great. By the use of compound cylinders any leakage in the high pressure cylinders is caught in the low pressure without loss.

Originally, it was the custom to lag the cylinders as in steam practice, but now it is found advantageous to leave them bare and to corrugate both sides and ends so as to present a maximum surface to the surrounding atmosphere while running, thus absorbing new energy.

In order that the method of making calculations may be fully understood we will figure out a haulage from the data given, most of the calculations being made with the slide rule, and though not extremely accurate they are in all cases taken above the actual values so as to be on the safe side.

EXAMPLE.—It is desired to haul trips of 60 cars, empties weighing 2,000 lb. and loads 6,000 lb. each, over a track having the following profile, and with one charge of air. All grades are in favor of loads.

PROFILE OF ROAD.

Grade %.	Distance.	Grade %.	Distance.	Grade %.	Distance.
1.3	800 ft.	0.3	700 ft.	2.4	400 ft.
2.0	600 ft.	1.77	1,025 ft.	3.5	425 ft.
1.3	800 ft.	0.9	300 ft.	1.2	820 ft.

The maximum grade being 3.5 per cent., and the car friction in this case being 1 per cent., the total resistance when ascending a 3.5 per cent. grade due to cars is, hence, $3.5 + 1 = 4.5$ per cent. Since it is desired to haul 60-car trips, and all grades are in favor of loads, it is only necessary to provide a locomotive capable of hauling 60 empties weighing 120,000 lb. up the above-mentioned grade.

The drawbar pull necessary to do this is 4.5 per cent. of 120,000 lb. = 5,400 lb. In general, it will require a locomotive having a weight on drivers of five times the tractive effort desired if steel tires are used, as is the practice in the construction of air locomotives, and 6 times the tractive effort if cast-iron chilled wheels are used, as is the practice in electric locomotives. We will, therefore, assume the necessary weight of the locomotive to give the proper adhesion as 32,000 lb., and we calculate that the tractive effort necessary to haul itself up the 3.5 per cent. grade would be $3.5 + .5 = 4$ per cent. (.5 per cent. covering the friction of the locomotive on the level) of 32,000 lb., or 1,360 lb., to which we add the necessary drawbar pull to haul the desired load, 1,360 + 5,400, and have a total tractive effort of 6,760, which is about the limit of our locomotive on dry rail with sand.

By consulting the table No. 1 we see that, at 100 lb. working pressure, a 10 in. $\times$ 14 in. 28 in. driver locomotive has a maximum tractive effort at $\frac{1}{2}$ in. cut-off, which is practically full stroke, of 5,280 lb., and by dividing this into our necessary tractive effort, we find that the necessary working pressure would be about 130 lb.

On this basis, we then make up the following table in order to ascertain the necessary air consumption:

GOING IN WITH EMPTIES.					
Grade.	Distance.	T. E.	Strokes.	Cut-Off.	Cu. In. Air Used.
1.3	800'	3,375	120	$\frac{1}{2}$ in.	126,000
2.0	600	4,450	80	$\frac{1}{2}$ in.	176,000
1.3	800	3,375	120	$\frac{1}{2}$ in.	126,000
0.3	700	1,880	105	$\frac{1}{2}$ in.	55,125
1.77	1,025	4,100	150	$\frac{1}{2}$ in.	315,000
0.9	300	2,750	40	$\frac{1}{2}$ in.	42,000
2.4	400	5,075	60	$\frac{1}{2}$ in.	157,600
3.50	425	6,760	65	$\frac{1}{2}$ in.	239,000
1.2	820	2,220	50	$\frac{1}{2}$ in.	52,600
COMING OUT LOADED.*					
0.3	700	2,800	105	$\frac{1}{2}$	110,000
20 per cent. additional					1,399,125
Total					279,825
					1,678,950 cu. in.

This equals 975 cu. ft. at 130 lb. pressure used in hauling the required loads on a single round trip. Since we should return

*Returning with loads, it is possible that there is only one grade that the trip will have to be hauled.

to the starting point with 130 lb. in the locomotive storage, it is evident that the volume of the tanks must allow for the use of 975 cu. ft. in addition to 1 volume at 130 lb.

Let V = volume of storage on locomotive;
 P' = pressure of storage on locomotive;
 p = working pressure;
 V' = volume at working pressure necessary to do the work required.

Then the product of the volume of the locomotive storage by its pressure must equal the sum of the volume necessary to do the work required multiplied by the working pressure, and the locomotive storage volume by the working pressure, thus,

$$P'V = pV + pV', \text{ or, } V = V' \frac{p}{P' + p}.$$

$$\text{If } P' = 650, \text{ then } V = 975 \frac{130}{650 + 130} = 244 \text{ cu. ft.}$$

With one locomotive of this kind in service and making trips every 30 minutes, we must arrange for a compressor capable of compressing 975 cu. ft. at 130 lb. in this time. Since it is customary to rate compressors at their capacity in free air per minute, the above is equivalent to $\frac{975 \times 130}{14.7 \times 30} = 288$ cu. ft. free air per minute.

This must be compressed to 800 lb. in the compressor, and stored in stationary storage. If X is the volume of the stationary storage, $P' = \frac{pV + PX}{V + X}$.

$$X = V \frac{P' - p}{P - P'}, \text{ or } X = 244 \frac{650 - 130}{800 - 650} = 846 \text{ cu. ft.}$$

The length of the haulage is 5,385 ft., hence the cross-section of the pipe necessary to furnish the requisite storage is

$$\frac{846}{5,385} = .157 \text{ sq. ft.}$$

From table No. 2 this would require a $5\frac{1}{2}$ in. pipe, but for practical purposes it is possible that a 5 in. pipe would be selected.

 TABLE NO. 2.
 STANDARD STEAM AND EXTRA STRONG PIPE USED FOR COMPRESSED-AIR HAULAGE PLANTS.

Trade Diameter. In.	Cu. Ft. in 1 Lineal Ft.	Lineal Ft. Necessary to Make 1 Cu. Ft.	Steam.		Extra Strong.		Trade Diameter. In.
			Thick-ness.	Weight per Ft.	Thick-ness.	Weight per Ft.	
2	.0218	45.41	.15	3.61	.22	5.02	2
2 $\frac{1}{2}$	.0341	29.32	.20	5.74	.28	7.67	2 $\frac{1}{2}$
3	.0491	20.36	.21	7.54	.30	10.20	3

6	.1963	5.10	.28	18.80	.43	28.60	6

Table No. 3 gives the horsepower necessary to compress 100 cu. ft. free air per minute, and from it we see that it would require $2.88 \times 32.5 = 93.6$ H. P., hence, we would be compelled to arrange for a boiler capacity of practically 100 H. P., provided we used a three-stage compressor, as is the general custom.

 TABLE NO. 3.
 HORSEPOWER NECESSARY TO COMPRESS 100 CU. FT. OF FREE AIR TO VARIOUS PRESSURES AND WITH TWO-, THREE-, AND FOUR-STAGE COMPRESSORS.

Gauge Pressure.	Horsepower Necessary.			Gauge Pressure.	Horsepower Necessary.		
	Two-Stage.	Three-Stage.	Four-Stage.		Two-Stage.	Three-Stage.	Four-Stage.
100	15.7	15.2	14.2	900	36.3	33.7	31.0
200	21.2	20.3	18.8	1,000	37.8	34.9	31.8
300	24.5	23.1	21.8	1,200	39.7	36.5	33.4
400	27.7	25.9	24.0	1,400	41.8	37.9	34.5
500	29.4	27.7	25.9	1,600	43.0	39.4	35.6
600	31.6	29.5	27.4	1,800	44.3	40.5	36.7
700	33.4	31.2	28.9	2,000	45.4	41.6	37.8
800	34.9	32.5	30.1	2,500		43.0	39.0

In the use of such high pressures too much care cannot be given the construction of the pipe line. It is found necessary to use specially designed flanges, bends made from the same kind of pipe as that composing the line and "tees" of specially heavy construction.

The flanges should average about 250 apart and all joints

screwed as tight as possible. It is preferable to support the pipe near the roof on posts specially set for the purpose. If laid on the ground they will soon deteriorate from the moisture collecting on them. There should be drip cocks at all low points so that the pipe can be drained from time to time. Where there is a large amount of dust in the atmosphere from which the air supply comes it is good practice to filter the air through water and although this method thoroughly saturates it with moisture yet it produces no serious trouble in compressing.

Production of Coal, by States.

By E. W. Parker.*

Including an insignificant product from Idaho and the Territory of Alaska, there were thirty States and Territories that contributed to the output in 1899, as in the preceding year. Of these thirty States, nineteen produced over 1,000,000 tons each in 1899, seven had an output exceeding 5,000,000 tons each, four exceeded 10,000,000, and two—Pennsylvania and Illinois—exceeded 20,000,000 tons. As is well known by all familiar with the coal trade, Pennsylvania stands preeminently at the head of the coal-producing States. The combined output of anthracite and bituminous coal in Pennsylvania has for many years exceeded 50 per cent. of the total output of the United States. The lowest percentage contributed by Pennsylvania in any of the years for which statistics are available was 52, in 1884 and 1888, while in 1880 it was as high as 65. In 1899, 53 per cent. of the total product was from Pennsylvania mines; 29 per cent. was Pennsylvania bituminous coal and 24 per cent. Pennsylvania anthracite. With such a record it is not probable that Pennsylvania will be supplanted as the leading coal producer during the next fifty or one hundred years. It has been estimated that at the present rate of consumption the anthracite fields of Pennsylvania will last from one hundred and fifty to two hundred years. And while industrial activity does not affect anthracite operations as much as it does bituminous mines, the production and consumption is stimulated in seasons of business revival such as that which prevailed during the past year. Anthracite production in Pennsylvania in 1899 increased 13 per cent. over 1898, as compared with an increase of 13.8 per cent. in Pennsylvania bituminous coal and a gain of 16 per cent. in the total bituminous product of the United States. Anthracite coal is becoming more an article of domestic consumption every year, while its use under boilers and for manufacturing purposes is being supplanted to a large extent by soft coal. It is not to be expected that its production will increase in the same proportion as bituminous coal, but with our increasing urban population its use as a domestic fuel may continue to increase for at least some time to come. Nor is it possible to predict what the rate of increase, if any, is going to be, but it is probable that for the next fifty years at least 20 per cent. of our total product will be made up of Pennsylvania anthracite. The State will continue as the leading coal producer for many years, if the history of the past may be taken as a basis for judging of the future.

Next in importance to Pennsylvania as a coal producer is Illinois, whose product in 1899 was 24,439,019 short tons, equivalent to 9.6 per cent. of the total product, and a gain of nearly 6,000,000 tons over the State's output in 1898. West Virginia, the third State in importance as a coal producer, increased her output 15.3 per cent., from 16,700,999 short tons in 1898 to 19,252,995 short tons in 1899; and while this product in 1899 exceeded that of Illinois for 1898, the latter's increased output in 1899 continues the State in second place, with a lead of over 5,000,000 tons ahead of West Virginia. Ohio remains in undisputed possession of fourth place, with a product of 16,500,270 short tons in 1899, a gain of nearly 2,000,000 tons, or 13.6 per cent. Alabama remains as firmly fixed in fifth place, with a total of 7,593,416 short tons in 1899, against 6,535,283 tons in 1898, recording an increase for last year of over a million tons.

It will be observed that all of these five leading States are east of the Mississippi River, and all but one, Illinois, belong to the Appalachian system. The sixth State in importance is Indiana, also east of the Mississippi River. Iowa, the most important coal-producing State west of the river, is seventh in the list of all the States, having displaced Maryland in 1899. Following Iowa are, in order, Maryland, Colorado, and Kentucky, contending for supremacy, each with a product exceeding 4,500,000 tons and less than 5,000,000.

Continuing the Mississippi River as a dividing line for a geographical distribution of the product between the eastern and western States, it is found that the production of the States east of the river was 224,096,219 short tons, or 88.3 per cent. of the total, in 1899, as against 193,793,334 short tons, or 84.3 per

cent, in 1898. The western States produced 29,643,773 short tons, or 11.7 per cent., in 1899 and 26,181,333 short tons, or 15.7 per cent., in 1898. Subdividing the eastern division into northern and southern States by the Potomac and Ohio Rivers, we find that the States north of the boundary produced 187,031,987 short tons, or 73.7 per cent., in 1899, as compared with 161,575,292, or 65 per cent. of the total, in 1898. The southern States produced 37,064,232 short tons, or 14.6 per cent. of the total, in 1899, and 32,218,042, or 19 per cent., in 1898.

The percentage of increase in production of the three divisions from 1898 to 1899 was as follows: Northern, 15.80; southern, 15.04; western, 13.22.

John A. Roebling's Sons' Exhibit.

The John A. Roebling's Sons Company, of Trenton, New Jersey, has received for its exhibit at the Paris Exposition two "Grand Prizes" and two gold medals, the highest honors within the gift of the Exposition authorities.

The Roebling display at the Exposition consists of two exhibits. One shows the product of the company's electrical department, and the principal feature of it is a full size model of a section of underground trolley track, illustrating the communications with the conductive bars and the lead-encased cables which transmit the current to the cars by means of connections known as ploughs.

The value of this exhibit rests on its showing the actual piece of underground trolley with the pavement cut away and is very instructive both to engineers and to the general public.

All kinds of telephone wires and cables are also shown with the means of connecting up and mounting.

Besides this there are very beautiful samples of every variety of wire used in electrical industries, all kinds of which are manufactured by the Roebling Company.

The most recent developments in electrical cables for carrying currents of the highest tension or greatest number of volts are illustrated in full size pieces.

This exhibit met with such favor with the jury that it was awarded a "Grand Prize" the highest award conferred by the Exposition authorities.

The second exhibit is in the department of metallurgy, and gives a comprehensive view of all the products of the Roebling works with the exception of the electrical conductors.

The United States Paris Exposition Commission approached the Roebling Company about a year ago to sound it with reference to the installation of a striking feature in the nature of a trophy. The Roebling Company consented to erect for the purpose a large model of the Brooklyn Bridge.

This is an exact representation of the famous suspension bridge, and surmounts the exhibit proper.

The first model of the bridge that was built for the Exposition was lost with the unfortunate "Paulliac" which was reported near her destination some six days after sailing and was never heard from afterward.

The Roebling Company, however, built a second model in six weeks and had it in its place about a month after the Exposition opened. The bridge was entirely built at the Roebling plant and is very graceful and pleasing to the eye.

Several cases with glass doors and shelves, form a part of the exhibit and contain samples of every variety of steel and copper wire from the largest sizes made, to wire with a diameter of $\frac{1}{100}$ of an inch. This latter is so fine that it is impossible to detect it between the fingers. It is half as thick as the finest human hair and a mile of it weighs about a quarter of an ounce. It is drawn through diamond dies, and is a good example of the skill displayed by the workmen in the process of manufacture.

The Roeblings are famed all over the world for the high quality of their wire ropes and cables, and these products of their mills are given a very prominent place in the exhibit.

There are also two full size sections of the cables of the Brooklyn Bridge.

The Roeblings were awarded for this exhibit a "Grand Prize" and a gold medal.

The company has exhibited at all of the prominent expositions for a number of years and possesses many awards conferred, including gold and other medals. At the Centennial, at the World's Fair in Chicago and at the Philadelphia Export Exposition, the excellence of its manufactures was generously acknowledged.

The Roebling Company in the last two years has built a large wire mill, probably the most extensive single mill in the world, and has added a number of buildings for various purposes. The company has in its employ about 3,000 operatives, and is at present more than doubling its office accommodations, and is building a new mill for electrical conductors which will increase the capacity of that department about 30 per cent.

* Extract from "The Production of Coal in 1899," U. S. Geological Survey Report, Washington, D. C.

NEW INVENTIONS.

EDITED BY H. M. LANE, M. E.

Complete specifications and drawings for any of the following patents can be obtained from the COMMISSIONER OF PATENTS, WASHINGTON, D. C., at the following rates:

Single copies.....	5 cents each.
Copies by subclasses.....	3 cents each.
Copies by classes.....	2 cents each.
An entire set of patents.....	1 cent each.

DREDGING APPARATUS.

No. 657,247. A. McDougall, Duluth, Minn. *Patented Sept. 4, 1900.* This invention is intended to cover certain features of a dredging apparatus for working placer deposits, the object being to work out a portion of the meadow by removing practically all of the gravel from the bed rock while the dredge floats upon the water in the pit. In the meanwhile an auxiliary pit or reservoir is dug to one side to contain a supply of water. The pit is then pumped out, the dredge supported upon spiles or spuds and the bed rock cleaned, water for this purpose being obtained from the reservoir. The patent is intended to cover this feature and also the use of jets of water under pressure for loosening the ground at the point at which the dredge operates.

This feature is illustrated in Figs. 1 and 2. Fig. 1 represents a side elevation of a portion of the dredge scow *A* which is supported by spuds as shown. Upon this scow is placed a suitable centrifugal pump *1*, forcing water through a flexible tube *2* to the head of the ladder supporting the bucket elevator. Along the side of this ladder permanent pipes *3* are arranged which are provided with nozzles *4* at their lower end. During the excavation of the pit, jets of water from these nozzles aid the dredge in loosening and removing the soil. After the pit has been excavated and the bucket elevator is being used to clean bed rock the nozzles may be removed and the hose attached to the ends of the pipe as shown by the dotted lines *5*, in Fig. 2. This hose is provided with a nozzle *6* and is used for washing the material on the bed rock into the pit in which the bucket elevator is operating. The centrifugal pump *1* may also be used for throwing an extra supply of water through the sluice *0* by providing a 3-way valve *15* at the head of the ladder and a pipe as indicated by the dotted lines.

ENDLESS CONVEYER.

No. 657,048. A. M. ACKLIN AND W. J. PATTERSON, PITTSBURG, PA. *Patented, Aug. 28, 1900.* The conveyer covered by this patent is intended to be used in connection with a casting machine and has certain novel features for removing the heat and overcoming expansion. In the accompanying figure, *a* represents suitable supports for carrying the conveyer tracks *d* and *d'* for the return conveyer and the tracks *c* for the loaded conveyer. The conveyer carries suitable

molds which are filled from a ladle *i* or by any other convenient method. A portion of the conveyer adjacent to the filling end is submerged in the tank *b* which contains a suitable cooling solution. The discharge end of the conveyer is elevated and passes about a wheel *f'* which may be a driving wheel, the other end of the conveyer being supported by a suitable wheel *f*. In order to overcome the expansion of the chain the return track may be provided with a gap *e* situated

between the portions *d* and *d'*. As the conveyer expands it will sag further into this gap. If desired, the gap may be replaced by a sag in the track which is made to conform approximately to the greatest sag in the conveyer, so that as the conveyer cools it will lift clear of this sag in the track. The conveyer chain proper may be made of any suitable design, as, for instance, links *g* may be carried upon the rollers *h* the axes of which form the pins for connecting the links.

SELF-ACTING MINING-DOG.

No. 656,279. W. A. WILSON, MURPHYSBORO, ILL. *Patented Aug. 21, 1900.* This invention provides a device for automatically loading the cars onto the cage at the bottom of a mining shaft, and is illustrated by the

two accompanying figures. In both figures there is a car upon the cage *A* ready for hoisting. The cage in its descent strikes the lever *B* which is fulcrumed at *C* and connected at *D* to the pitman *F*. This pitman throws the piece *G* in such a manner as to draw the dog *G'* away from before the front wheel of the first car on the inclined track, thus allowing it to run onto the cage as shown. In order to prevent the next car from following, the dog *G'* is thrown in as shown. When the cage is hoisted the lever *B* is released and the spring *E* immediately returns the lever *G* to its place. This removes the dog *G'* from before the carwheel allowing the car to pass on until the wheel rests against the dog *G'*, so that the apparatus is ready to load another car as quickly as the cage comes down again.

SLATE AND COAL SEPARATING DEVICE.

No. 655,161. P. F. POORBAUGH, ALLEGHENY, PA., ASSIGNOR OF ONE-HALF TO FREDERICK C. MANCOURT, OF BELLEVUE, PA. *Patented July 31, 1900.* This invention is a continuous carrier adapted to separate coal from slate, the coal traveling in an opposite direction to that of the slate during the separating. The carrier for separating coal and slate consists of a pair of continuous strips *25* of suitable material mounted upon the drums *22*, *24*. Mounted on these strips is a series of rectangular inclined metal plates *26*, secured at their upper ends, to the strips *25*, as shown, and overlapping each other at their lower ends. The sides of these plates are bent at an angle, forming a flange to retain the coal and slate upon the carrier. The upper end of each of these angle portions of the plates *26* is cut away to permit of the overlapping of adjacent plates. The hopper *30* is provided with a hinged bottom *31*, forming a chute, and with a slide *32*, adjusted by means of bolts. The operation of the separator is as follows: The drums revolving move the carrier, and as the coal and slate are placed on the series of metal plates forming the carrier the coal will ride downward and be discharged over the drum at the lower end thereof, while the slate will be carried upward and be discharged at the upper end.

APPARATUS FOR LOADING OR UNLOADING MINE CAGES OR BUCKETS.

No. 654,270. JOHN F. MCKAY, OF PROSPERITY, MISSOURI, ASSIGNOR OF ONE-HALF TO JOHN RAYMOND AND CLAUD D. RAYMOND, OF WEBB CITY, MISSOURI. *Patented July 24, 1900.* A bucket attached to a rope by a bail is guided between two guides in the usual manner. The bucket is provided at opposite sides of its upper portion with rollers or wheels *6*, and it has arms *7* depending from its bottom and provided with openings for

the reception of a transverse rod 8. The ends of the rod extend outward beyond the arms and form an axle for a pair of lower rollers or wheels 10. The bail 5 is connected with the rod 8 at the outer faces of the arms 7 and is provided near the centers of its sides with bends 11 to enable it to clear the journals 6 and at the same time to lie centrally of

the bucket. The bucket swings outward on 8; inclined side tracks or rails 12 extend from the upper portion of the guides or ways to receive the upper wheels 6, as illustrated in Fig. 1, when the bucket reaches the limit of its upward movement. Pivoted switches are mounted adjacent to the side openings 14 to cause the upper rollers or wheels to move laterally through the openings 14. The lower depending arm of the switch, which is lighter than the upper outwardly-extending arm, is disposed across the guide or way, as shown in Fig. 2, when the switch is in its normal position, whereby it is adapted to switch the upper rollers or wheels upon the side tracks or rails. The further upward movement of the bucket causes the upper rollers to engage the arms 16, which are lifted sufficiently to throw 17 outward to a vertical position to close the side openings temporarily, as illustrated in Fig. 2. The arms 17 of the switches when arranged in a vertical position cause the lower rollers or wheels to move vertically in the guides or ways past the side openings of the same, to elevate and invert the bucket, and discharge the contents. The bucket is filled from a hopper, having an inclined bottom and located below the level at which the mining operations are carried on. The hopper is provided at its front, adjacent to the shaft, with a hinged gate 20, adapted to form a chute when the same is open, whereby the contents of the hopper will be discharged into the bucket. The gate or door is normally held in a vertical or closed position by a weight, attached to one end of a rope or other flexible connection, which passes over a pulley and is secured to the gate near its upper edge. The automatic opening of the gate is effected by means of a lever 26. When the bucket descends, the transverse rod or axle 8 engages the lever, which is arranged in an inclined position when the gate is closed and which is swung downward by the weight of the bucket to the position illustrated in Fig. 2. This brings the hinged gate in position for discharging the contents of the hopper into the bucket, and the capacity of the hopper should be substantially the same as that of the bucket, so that none of the contents will be wasted. As soon as the bucket rises with its load the weights automatically close the gate and swing the lever upward to the inclined position shown in Fig. 1.

CALCINING OR ROASTING FURNACE.

No. 658,580. A. E. JOHNSON, VICTOR, COLO. Patented Aug. 21, 1900. The accompanying figure shows a side elevation, partially in section, of

the furnace covered by this patent. The object of the invention is to do away with any mechanical rabblers inside of the furnace for stirring the ore, the ore being stirred and moved along the hearth by means of air blasts. The ore is introduced from a hopper 33, through the

funnel pipe 32, and falls upon the upper end of the hearth. From this upper shelf it is moved to the next shelf by blasts of air from the pipe 26 and from this to the succeeding shelves by successive blasts of air from the pipes shown. When the ore finally reaches the last shelf of the furnace it is thrown into the passage 13 and falls into the chamber 12 from which it is removed. Fire is maintained in the chamber 6, 7 being the grate bars and 8 the ash-pit. The fire passes over the bridge wall 19 and out at the end of the furnace at which the ore enters. The blasts of air not only move the ore, but furnish the necessary oxygen for its oxidation. In order to control the blasts the pipes are provided with valves which are controlled by levers 29. These levers are made heavy so that normally they hold the valves closed. An endless chain 31 is arranged to travel beneath the levers 29 and is provided with dogs 30 which engage and lift the levers, thus opening the valves and causing a series of jets of air to blow across one of the steps in the hearth. By this means the ore is moved slowly down the hearth one step at a time. The air blast is furnished by any suitable blower, as, for instance, 25.

PROCESS OF SEPARATING ORES.

No. 656,728. H. C. ROBINSON, CINCINNATI, O. Patented Aug. 28, 1900. This invention is intended to provide a method for separating gold

from placer material, or any other heavy material from a substance of less specific gravity. It consists of a vertical shaft 4 carrying a horizontal disk wheel 2 having an up-turned flange 3 at the outer edge. The material to be operated upon is fed from the spout 1 on the center of the disk. The disk is placed under water and rotated at such a rate that the centrifugal force will just cause the material to flow towards the circumference. A bank of soft material, such as sand, is maintained against the rim 3 so that any heavy particles such as metallic gold will bed themselves in this bank of soft material and ultimately lodge against the rim, while the lighter material will work up and discharge over the rim.

laying off along AB the distance $22A$ of Fig. 2. Clamp the set screw M ; then swing the lever arm laying off the given dip. Clamp the set screw at A . Find the intersection of DE and the edge AK at U in Fig. 1.

If now the T square FG is moved until its edge FG passes through U , it will then represent the projected vein $1'2'$ in plan.

The next problem is: If you have given on the map the ledge 12 and at a depth $22A$ the projected ledge $1'2'$, to find the angle of dip, as in Fig. 3. Along 12 place AB , then by the lever lay off along

tion of the line of intersection $55'$, and also its direction.

The method is as follows: As previously described, determine from 12 the line $1'2'$ for any depth as $22A$. Then for the same depth from 34 determine $3'4'$. Connect 5 or $5A$ and $5'$, which is the line required. To find the dip of the line $55'$, i. e. the angle $655'$ of Fig. 4, the method is as follows: In Fig. 5, after having laid off on line AB of the apparatus the distance $22A$ by the lever first mark the same by the edge DE of the T square at a point Z . Then place point Z on $5A$, Fig. 5, making ZD coin-

cide with $5A5'$; next swing the lever arm until AK cuts $5'$; clamp screw at A ; read off the required dip on the quadrant. By noting also the distance AU on the apparatus, which is equal to the distance $55'$, Fig. 4, we have the distance along the ledge following along the line of intersection.

The bearing of the horizontal projection of this line of intersection, $5A5'$ can also be read off on the quadrant.

If the problem of finding the line of intersection of two ledges having parallel strikes is required, the method just described must be modified.

Fig. 6 shows two parallel ledges and Fig. 7 the plan of the same. The solution is as follows: Place the line AB of the instrument on ledge 12 in Fig. 7, placing A on point 8 , then draw line 89 , cutting 34 at point 10 . From A lay off the dip a and draw line $8K$; also on ledge 34 from point 10 similarly draw line $10K$ laying off dip B . Find the intersection of lines $8K$ and $10K$ drawing line 56 through this point U and parallel to 12 and 34 . 56 is the horizontal projection of the line of intersection of the two parallel ledges having a dip of a and B .

The determination of lines of intersection of ledges is very important in the study of ore bodies, as usually along these lines there is an enrichment of mineral matter.

In making cross sections of ledges where the section plane is not at right angles to the strike of the ledge, this instrument can be used to advantage; the problem being simply that of finding the dip of the line of intersection of the two planes, one of them being vertical.

For finding the apex of a vein of known dip, the problem is the reverse of the problem solved before, with this difference, however: Instead of projecting down from an upper level, it is reversed. The instrument is reversed from the operation shown in Fig. 2 and Fig. 3.

For tracing the intersection of a vein on its dip with the contours given on a topographic contour map, i. e. to find the apex of the vein, which may be either a straight line or a curved line, the

FIG. 8.

operation is as follows: Let 12 of Fig. 8 represent the vein, say at the 100 ft. level, and having an elevation of 5,000 ft. above the sea level, and having a dip of 60 degrees from the horizontal. To find its intersection with the 5,120 ft. contour. Along the strike 12 place the line AB of the apparatus in Fig. 1; by means of the arm AK lay off the vertical interval between the vein at 5,000 ft. above the sea and the contour in question, on the line

AB , moving the T square ED to that point (Z in Fig. 1); then swing the arm AK to read the 60 degree dip. The point of intersection V of the edge AK and ZD is the point where the vein on its dip cuts the horizontal plane having an elevation of 120 ft. vertically above the vein at the 100 ft. level.

By moving the apparatus along the line AB , keeping this line on the strike line 12 , the intersection of the lines AK and ZD with the contour in question determine points on the required apex.

For the determination of the true dip and strike of slightly inclined strata, say a coal seam, with an ordinary compass and clinometer the problem can be quickly solved.

The observations by the compass and clinometer are as follows: From any point A on the strata take a reading of dip α degrees from the horizontal in the direction AB and also its bearing. Then in any other direction AC get the dip β and the bearing. So then the included angle of the bearings is d . If these bearings are plotted on a plan map, the solution is as follows:

With the vein projector along AB measure off the throw AB' for α degrees in 100 ft., and draw a line 12 at right angles to AB' ; similarly on AC for β degrees in 100 and draw line 34 through C' at right angles to AC' .

Find the intersection of lines 12 and 34 at K . AK is the horizontal projection of the true dip line; drawing a line $\perp$ to AK through A represents the strike of the strata. Since AK is the horizontal throw of the true dip line for 100 ft. vertical the angle of dip can be determined by the vein projector, Fig. 1. Make $AZ = 100$ ft., and $UZ =$ the length of the line AK just determined, then swing lever arm (Fig. 1) to the intersection and read the true dip on the quadrant.

For the calculation of the dip and strike of strata cut by vertical bore holes, the preceding problem solved shows the method of solution.

World's Product of Coal.

In the following table is given the coal product of the principal countries for the years nearest the one under review for which figures could be obtained. For the sake of convenience the amounts are expressed in the unit of measurement adopted in each country and reduced for comparison to short tons of 2,000 pounds. In each case the year is named for which the product is given:

THE WORLD'S PRODUCTION OF COAL.

Country.	Usual Unit in Producing Country.	Equivalent in Short Tons.
United States (1899)	long tons 226,558,564	253,739,992
Great Britain (1899)	long tons 220,085,308	246,495,839
Germany (1899)	metric tons 135,824,427	149,719,766
Austria-ungary (1899)	metric tons 87,746,963	41,652,569
France (1899)	metric tons 82,356,104	34,656,426
Belgium (1899)	metric tons 21,917,740	24,159,925
Russia (1898)	metric tons 12,862,038	14,173,960
Canada (1899)	short tons 4,925,051	4,925,051
Japan (1897)	metric tons 5,647,751	6,225,516
India (1899)	long tons 4,208,199	4,707,542
New South Wales (1899)	long tons 4,547,028	5,148,671
Spain (1899)	metric tons 2,742,889	3,022,113
New Zealand (1898)	long tons 906,778	1,015,591
Sweden (1898)	metric tons 236,277	260,448
Italy (1899)	metric tons 341,327	376,245
South African Republic (1899)	long tons 1,907,271	2,136,143
Queenland (1898)	long tons 407,819	454,757
Victoria (1898)	long tons 245,659	275,138
Natal (1898)	long tons 387,811	434,848
Cape Colony (1898)	long tons 171,301	191,857
Tasmania (1899)	long tons 44,141	49,138
Other Countries (a)	long tons 2,000,000	2,240,000
Total		797,062,775
Percentage of the United States		32

a Includes China, Turkey, Servia, Portugal, United States of Colombia, Chile, Borneo and Labua, Mexico, Peru, Greece, etc.

The preceding table shows that the United States has taken first place among the coal-producing countries of the world, our product in 1899 exceeded that of Great Britain, our only real competitor, by 5,494,632 long tons. In 1868 the coal product of Great Britain was 3.6 times that of the United States. In the same year the product of Germany was nearly 15 per cent. larger than ours. In 1871 we passed Germany, leading her in that year by about 10 per cent. In 1875 and 1876 the United States fell back to third place, but took second place again in 1877 and continued to gain in comparison with Germany, until in 1899 the product of the United States was 69 per cent. more than that of her former rival.

From 1868 to 1878 the product of the United States had increased from 28,258,000 long tons to 51,655,000 long tons. In the same time Great Britain's product had increased from 103,141,157 long tons to 132,612,063 long tons, so that her tonnage in the latter year was not quite 2.6 times as great as that of the United States. In 1888 the output of the United States had risen to 132,731,613 long tons, and that of Great Britain to 169,935,219 long tons, 1.3 times the product of the United States. In 1898 the tonnage of the two countries was, respectively, 196,405,953 and 202,054,516, Great Britain leading the United States by less than 3 per cent. In 1899 the positions held in 1898 were reversed, the United States leading Great Britain by a little less than 3 per cent.

In 1868 the United States contributed 14.35 per cent. of the world's coal supply; in 1878, 18.17 per cent.; in 1888, 28.52 per cent., and in 1899, 31.83 per cent.—U. S. Geological Survey Report for 1899.

Alabama Mining Methods.

Written for MINES AND MINERALS, by J. E. Strong.

The accompanying figure shows the common methods used in working the Alabama coals. The seams now working vary from 2 feet to 6 feet thick, and they pitch from 2° to 40°. Where the seams are thin the coal is hard and pillars of about 20 to 30 feet are used to support the roof. The thick seams are soft and easily broken, and much larger pillars are left. The character of bottom and top varies. Fireclay bottom and slate roof are usually found with the thick seams, and hard bottom and sandstone roof with the thin seams. The general plan of laying out the mine is to drive the slope straight with the pitch of the seam; this is usually on the butts of the coal. A single-track slope is 8 feet wide, and a double-track slope is 16 feet. Cross-headings are driven or turned from the slope water level every 300 feet; air courses are driven parallel on either side of the slope. Where an 8-foot slope is driven 30 feet of pillars are left between the slope and airway, and for a 16-foot slope, 30 feet of pillars. The size of pillars, however, depends largely upon the character of the roof and thickness and strength of coal. On the lower side of the

headings, pillars from 20 feet to 60 feet are left on the entry before turning the first room. The rooms are worked across the pitch on an angle of about 5° on the rail (A), when the coal does not pitch greater than 20°; where the pitch is greater, chutes are worked and the rooms are driven straight up the pitch (B). In a few cases, where the pitch is not greater than 15°, double rooms are worked with two roadways in each room (C). A rope with two pulleys is used and each track keeps the rib side of the room, the loaded car pulling up the empty on the opposite side of the room. Distance between room centers about 42 feet. Where single rooms are worked the room is driven narrow (8 feet wide) for 21 feet, when connections are made with the room outside of it; the room is then widened out to about 25 feet, sloping gradually until this width is attained, pillars of from 10 feet to 20 feet thick are left between the rooms, and crosscuts for ventilation are made about every 50 feet; every third or fourth room is driven through to the entry above; pillars are then drawn back to the entry stumps or pillars. The average cover over the coal now working is from 100 feet to 600 feet. Air courses usually have an area of 30 feet, and sufficient coal is taken out to give this area, the roof and bottom being left.

DREDGING FOR GOLD.

Facts in Regard to the Operation of Dredges on Placers at Various Places in the West.

By W. S. Russell, Chief Engineer Vulcan Iron Works Co., Toledo, Ohio.

Dredging for gold is a new opening for the profitable investment of capital, and it has been demonstrated that under proper management it is a safe business proposition.

The elevator bucket dredge has proved to be the most suitable machine for deep placer mining, and with it ground can be worked that heretofore has been beyond the reach of the ordinary methods previously employed.

There have been but few failures in deep placer dredging, whereas it has been estimated that less than 25% of quartz mining ventures have been successful, and more than 75% have been failures. The reason is plain, in quartz mining you are working in the dark, searching for a hidden vein; signs and indications may seem favorable, but fail in the end after expending thousands of dollars.

In placer mining, however, you can test the ground at a definite expense, knowing beforehand what that expense may be. The "Keystone" driller will put a hole down through the sand and gravel to bed rock at a depth of 40 feet which is about the limit for an elevator bucket dredge. This method is not expensive, and will answer for preliminary prospecting, after which if conditions are favorable, a number of test pits, say 4 ft. by 6 ft. may be sunk to bed rock and every foot of the gravel washed out and its gold-bearing value known.

Not only this, but the nature, thickness, and density of each stratum, whether hard or soft, may be shown, also the proportions of sand, gravel or boulders. These conditions must be known in order to determine upon a suitable style of elevator bucket dredge of proper size and construction, adapted to handle the particular piece of ground under survey in the best and most economical manner.

The best grounds in Colorado, Montana, Idaho, and California lie in the valleys of small creeks and gulches and are universally nearly level. Some are in cultivation, and hundreds of acres of alfalfa, hay and meadow grass are grown on them. The depth of sand and gravel varies from 15 to 30 ft. The bed rock is usually soft, of a clayey nature, sometimes of decomposed granite.

The first elevator bucket dredge operated in this country was built at Bannock, Mont., on Grasshopper Creek, in 1895, by H. J. Reiling and others, was named the F. L. Graves, but was found entirely too light to dig the gravel; it was rebuilt in 1896 and became successful in 1897, earning over \$1,000 per day.

That same year, the dredge A. F. Greater was built and was a success from the start, although a large amount of money was expended in readjusting the machinery to suit the ground, but it proved so rich that it is reported as high as \$5,000 per day was taken out. The company is now wealthy.

Then followed the dredges "Maggie A. Gibson," the "Bon Acord," and the "Geo. F. Cope," all located on Grasshopper Creek, below Bannock. These dredges met with varying success. The "Maggie A. Gibson" ran into poor ground, was finally dismantled and moved to the Ruby Valley, in Montana. The "Bon Acord" was a failure from its conception.

The two miles of creek canyon with 40 ft. to bed rock was too narrow, the bed of the creek was too rough and rocky with huge boulders and cross reefs, to admit of working at all with an elevator bucket dredge.

It must be understood that there was no prospecting of any consequence done in Grasshopper Creek at Bannock, the creek being too wide to admit of test pitting or drilling. Mr. A. F. Greater felt sure there was gold there for he had been there since the early '60's and had seen millions taken out with the rocker and sluice box, in the shallow workings. He secured the most favorable ground and made a fortune.

The dredge "Geo. F. Cope" is now a success owing to the good management of E. L. Hall, Supt., after a year's work in changing and reconstructing the machinery to adapt it to handle the ground in a proper manner.

These particulars concerning the Bannock dredges are mentioned to show the necessity of careful inquiry and study of conditions surrounding a placer property, as well as the systematic and intelligent prospecting.

During the past two years, a number of elevator bucket dredges have been put out and are now under successful operation. The North American Gold Dredging Co. at Breckenridge, Colo., have two elevator bucket dredges, at work in 40 ft. ground. The Boise Dredging Co., of Philadelphia, Pa., have three elevator bucket dredges near Centerville, Idaho, in the Boise Basin, in 28 ft. ground. These are all operated by electric power.

The Horse Prairie Gold Dredging Co. have the new elevator

dredge "Isabel Brenner," in operation at Horse Prairie, Mont., about 18 miles west of Red Rock. The Pacific Gold Dredging Co., of Chicago, have a large elevator dredge near Salmon Creek, Idaho, working on the McNutt placer grounds. The Conrey Placer Mining Co., of Boston, Mass., have a large single lift elevator dredge, working in the Ruby Valley, at the mouth of Alder Gulch, 7 miles from Virginia City, Mont., in 30 ft. ground. The dredge "Maggie A. Gibson" is also working on the Conrey property.

The gold is a medium grade and very evenly deposited. The pay gravel is as yellow as saffron, and very hard to dig. It is also coarse with small boulders.

The Boston and Idaho Gold Dredging Co., of Boston, Mass., has operated a California dredge at Idaho City for the past two years, having met with good success, after the first few months of trial, in 20 ft. ground. They have a small Risdon elevator dredge which does fairly well, as the gravel is small and easy to dig, with a large proportion of sand. A rather remarkable feature of this proposition is that the gold saved exceeds the prospects by about 10%. This company is now experimenting with a large dipper dredge which was started up this spring, but with results as yet undetermined.

There are about fifteen dredges working in California, up the Sacramento Valley, from Folsom, on the Feather River, northward, including the Yuba River, Poker Bar, and Trinity River. At or near Oroville, there are seven dredges, of which five are elevator and two bucket dredges. Most of these are small, of the Risdon type, with buckets of three cubic feet size and 1,000 cu. yds. daily capacity.

It has become evident to all the dredge companies that their machinery is to light and improperly proportioned, and that there is a great expense in making repairs, as the dredges in most all cases are in remote places a long distance from any railroad. In view of this and many other facts, it is evident that there is a necessity for improvements in elevator bucket dredge machinery.

The Vulcan Iron Works Co., of Toledo, Ohio, has had a large experience in this line, dating over several years of very close study of the different requirements in different parts of the West. Not only that but this company has had an experience of something like 30 years building dipper dredges and steam shovels, and has a wide reputation and has the credit of having designed and built the monster 95 ton steam shovel for digging iron ore in the Minnesota mines and others for stripping phosphate grounds in South Carolina, and other states. In fact they build the greatest variety of steam shovels of any concern in the business.

After a close and practical study of the elevator bucket dredge and the subject of placer mining for several years, and after building and operating dredges of both the single and double lift type in Montana, Idaho and other parts of the west the Vulcan company has now designed several styles of elevator bucket dredges on new lines, with new ideas and improvements, and which though being original and simple, embody great strength, as well as ease and economy in operation.

The dredges heretofore built have been fitted with either 3 cu. ft. buckets, having a capacity to dig 900 cu. yds. per day, or 5 cu. ft. buckets having a capacity to dig 2,000 cu. yds. per day of 22 hours.

The new "Vulcan" elevator bucket dredge will be fitted with buckets holding 10 cu. ft. each and have a capacity to dig 5,000 cu. yds. of material every 22 hours. The expense of operation will be but very little more than the old style dredge of less than half the capacity.

This dredge will have about 300 horsepower, will be equipped with the most modern engine power, surface condenser, steel gearing and sprocket wheels, improved steel tumblers and bucket chains, ball bearing grizzly, steel sluice boxes, electric light plant, etc. The hull will be extra strong with water tight compartments, length about 120 ft., beam 44 ft., draft 4 ft. This dredge will have power to handle very hard material and boulders, and will dig the ordinary placer gravel at a cost of 2½c. per cu. yd.

The great aim of the concern mentioned is to obtain a careful survey of the ground to be worked and then build a dredge suitable for the ground, in order to avoid the expense of changing and reconstructing the dredge after it has started to work, which, by the way, is very painful and discouraging to the stockholders.

A dredge that will work successfully from the start and produce a daily winning of the golden dust is the one to be greatly prized by those who invest in such ventures.

Profits in elevator dredging depend on the richness of the ground and economy in operation. A dredge handling 2,000 cu. yds. per day of 24 hours at \$1 per yard, will earn \$2,000. There is a big profit in 50c. ground and a good profit in 25c. ground, which would yield \$500 per day. There is plenty of 25c. ground in the west, not being worked at all. The Souther dredge, working near Idaho City, Idaho, is now making over \$300 per day, above expenses. The three Bannock, Mont., dredges "F. L. Graves," "A. L. Greater," and "Geo. F. Cope" have earned from

\$500 to \$700 per day during this season. The Conrey Placer Mining Co.'s dredge "Col. Gordon," in the Ruby Valley, Mont., has earned from \$500 to \$600 per day this season. The Pacific Gold Dredging Co.'s dredge at Salmon City, as well as several

others have been more or less successful, but it is difficult to obtain information as to their earnings.

The following illustrations show typical elevator bucket dredges working under various conditions.

WELSH MINE CARS.

A Detailed Description of Some of the Various Types of Cars in Use in South Wales.

By Mr. J. Fox Talbot.*

The success of a colliery depends upon attention to details, and the faulty design of a mine car or gauge of rails is sufficient in the present time of large quantities and small profits to turn the scales against the colliery proprietor. The object of this paper is not to lay before you a model or perfect tram, but rather to draw attention to the various sorts and conditions of trams prevailing in the South Wales coalfield, and, as these different designs are not called into existence from the different conditions or exigencies of the respective collieries, they cannot all be correct.

The tendency of the age is to increase the carrying capacity and reduce the ratio of weight of car to weight carried, but in some of the most modern cars the latter point appears to have been somewhat overlooked, and it would be interesting to learn wherein the advantages of adopting such a heavy design of car come in. It will probably be argued that the weight is necessary to secure the required strength to withstand the rough usage to which cars are subjected in collieries, and no doubt this is the cause of the existing heavy cars. To add weight to a badly designed car to increase its strength is one way of surmounting the difficulty, but is it the best way? Does not the extra weight cause an inherent weakness in the car itself?

Would it not be better to adopt a car of such a design as would give the required strength without adding to its weight? Having found such a car amongst the existing cars or upon an improved design, would there be any advantage in universally adopting such design, as far as circumstances will allow, at the various collieries?

In the twenty-six cars of which particulars are given in the tabulated statement, representing a fair sample of those used in the larger collieries of the coal-field, the weights of the cars vary from 6½ cwt. to 12½ cwt., and their coal-carrying capacity, allowing for two feet of "topping" and calculating 56 lb. to the cubic

foot, from 24.16 cwt. to 40.64 cwt. (see columns A and B in tabulated statement).

The outside length of cars varies from 69 in. to 84 in.; the outside width varies from 37 in. to 49 in.; the height from rail varies from 29½ in. to 38 in., and the wheel centers vary from 19 in. to 24½ in.

The gauges of the wheels vary from 24 in. to 37½ in., showing sixteen different gauges as follows:—One 37½ in., five 35½ in., two 34½ in., one 34 in., one 34 in., four 33½ in., two 33 in., one 32½ in., one 32 in., one 31½ in., two 31 in., one 30 in., one 29½ in., one 28 in., one 27½ in., one 24 in.

In four cases the gauge of rails is one inch wider; in twenty, half an inch wider; in one, quarter of an inch wider; and in one, one-eighth of an inch wider than that of the wheels.

The diameters of the wheels vary from 12 in. to 17½ in. as follows:—One 17½ in., nine 17 in., one 16½ in., four 16 in., two 15½ in., four 15 in., one 14 in., one 13½ in., three 12 in., or nine different diameters, comprising one "fixed" cast iron wheels, four "loose" cast iron wheels, six "fixed" steel wheels, six "loose" steel wheels, nine "Rowbotham" wheels.

It is interesting to note the different kinds of rails and ties used at the various collieries. The sections of rails vary from 18 lb. to 35 lb. for ordinary roads, and up to 41½ lb. for main roads. There are twelve cases of bridge rails varying from 18 lb. to 24 lb., and twenty-six cases of T-head rails varying from 18 lb. to 41½ lb.

The bridge rails are generally secured to ties with nails, the T-head rails by spikes, and the heavier sections by chairs and fishplates, or spikes and fishplates.

Timber ties are most general, but there are a considerable number of wrought iron and steel of various patterns, and combined ties of wrought iron or steel with cast iron chairs.

T-head rails and combined ties appear to be gaining favor. One advantage of the T-head rail is that you can form your permanent partings at pit bottom and main junctions out of the rails instead of having castings; the former certainly work much smoother and do not wear to the same extent as castings.

Combined ties, of which cast-iron chairs cast on to a wrought-iron or steel tie is a good type, being practically unbreakable and as lasting as the rail itself, have the advantage of maintaining a regular gauge, and reduce the height quite 2 inches as compared with a wooden tie, which makes a material difference in ripping,

* Not compared with above cars.

and enables a heavier load to be carried; they are also better for getting cars on the rails when they go off the road. Another advantage is, there are no rails or spikes for the horses to pick up.

Number 28 on tabulated statement and Plan 28 shows a steel car, with a weight of 9 cwt., having a length over all of 75 in.; width, 46 in.; height off rail, 36 in., representing a cubical capacity, after allowing for 2 ft. of topping, of 73.51 cubic feet, or a load of 36.75 cwt., and if built to following specification could be placed on rail at the workshop at \$22.50 per car, and allow a fair margin for profit. This is based upon prices for steel and iron prevailing in 1898. The following are the specifications:

SPECIFICATION.

Back-end binder, 2½ in. × 2½ in. × ½ in.
 Middle binder, 3 in. × ½ in.
 Front binder, 3½ in. × ½ in.
 Buffer plates, 2 ft. × 6 in. × ½ in., secured by ½ in. bolts.
 Top rails, sides, and ends, 2½ in. × 2½ in. × ½ in., special angle.
 Door hinges, 2½ in. × ½ in.
 Side hinges, 2½ in. × ½ in.
 Door pin, 1 in. round.
 Door fastener, 1 in. round.
 Door fastener guide, 2½ in. × ½ in.
 Staple for blocking on, 2½ in. × ½ in.
 Drawbar, 4 in. × ½ in., doubled back at ends.
 Pedestal gland, ½ in. round.
 Frame bolts, ½ in. round.
 Frame sides, ½ in. deep × 3½ in. wide.
 Frame, distant pieces ½ in. deep × 3½ in. wide, tenoned and tusked into sides.
 All of pitch pine.
 Wheels, steel, 15 in. diameter, 2 in. axles, 7 curved arms: width of tread, 2½ in. + flange ½ in. = 3 in. wide.
 Pedestals, cast iron.
 Body of car, drawbar, and pedestals secured to pitch pine frame by 17 ½ in. bolts.
 Rivets, ½ in. diameter.

If design of car 28 is fixed with 12-in. wheels instead of 15 in., which would allow an additional depth of 1½ in. in the body of the car without increasing the height off rail, the load could be increased.

Car No. 1 on tabulated statement is that in general use at the Ebbw Vale Company's collieries. The gauge of wheels is only 24 in., which is an objection, as the horses, especially when first put to work underground, are very apt to tread on the rails, which on a down gradient is a prolific source of accidents; in other respects the car gives excellent results, it runs easy, and keeps the road well, even at high velocities. The life of the car compares favorably with the old-fashioned ordinary iron one, and the cost of maintenance is in favor of the former.

If any particular design of car became practically universal in South Wales the first cost would be considerably reduced, from the fact that, if the various sections and lengths of steel bars and plates were in more general demand, they could be supplied at a lower rate.

A great advantage in the universal adoption of one design of body of car would be that colliery owners could be supplied by the makers with the various sections of bars, angles, and plates to the required sizes, at a minimum price for repairs, which would also curtail the cost of labor in repairing the cars at collieries.

An objection that will possibly be raised to class of car No. 28 is that it is too light or not sufficiently strong to stand the rough usage it would be subjected to in South Wales collieries, but from over seven years' experience that the writer has had with these cars he does not find that they are damaged or entail more repairs than the heavier car. This is accounted for by the car being built to a stronger design, and therefore does not require such heavy

sections of steel as the car in ordinary use; also to the fact of the car having a timber frame, and, being provided with buffers, the bodies of the cars seldom come into collision; the timber frame receives the blow, and if the timber frame is broken, which is very unusual, it can readily be replaced by a new frame and at considerably less cost in labor than repairing a car all of iron or

PLAN 28.—DESIGN OF COAL CAR.

steel, which, if badly bent in a collision, would require to be cut up and rebuilt.

It is usual to keep a few timber frames in stock, on the pit top. The price for fixing a new frame is less than \$.28 per car.

An advantage in this design of car is that the buffers prevent breakage of the coal. When cars come together the force of the blow is largely taken up by the timber frame, and is not conveyed to the coal to the same extent as it is in a car with an iron frame, and especially in cars without buffers, where the coal itself comes into contact.

This design adapts itself better for the use of doors instead of bars at the end, which are often bent and cannot be properly secured, allowing the small coal to get out in transit, which is a consideration, especially in seams where cars have to travel over heavy gradients.

An important point is the weight of a car; for instance, in the case of a system of haulage where it is found that the maximum train conveyed by a hauling engine is at present limited, if the weight is reduced, the journey could be increased, and thus the output of a district probably increased in proportion.

This would depend upon other circumstances as well; at the same time it is not unreasonable to assume such would be the case at many collieries.

A more important point in the South Wales coalfield, where such a large number of horses are employed, is the increased load of coal that would be conveyed by each horse, which represents either an increased output or a reduction in the number of horses.

A train for a horse working on a level is generally regulated by the number of empties the horse can take in rather than by the full load, and an increase of one car in each journey would represent a substantial gain.

The reduced manual labor in dealing with the cars on the pit bank, the pit bottom, and in the stall roads, where miners can and do more readily take their cars from the heading to the face of the coal, would prevent the necessity in many cases of the horses going into the stalls at all.

In collieries where the carrying capacity of the car can be increased a substantial gain would be found from the fact that the miners would still fill the same number of cars, and on five cars would probably send out 10 cwt. more coal, increasing the output 0.25 ton per miner per day. The writer has found from experience that in this way alone it has more than repaid the cost of substituting an improved car, the latter being introduced as renewals were required.

An important point in connection with cars is the lubrication, and fixed wheels offer better facilities for lubricating more effectually and also more economically than loose wheels.

In the suggested design of car No. 28 the gauge of 34 in. and 15-in. wheels are selected because fixed wheels of this diameter are at present extensively used on this gauge in the district and give satisfaction. The writer's experience is in favor of 12-in. wheels, which have always given entire satisfaction and have the advantage of reducing the height of the car or increasing the capacity with the present height.

The question of different gauges and loose wheels need not interfere with the introduction of this design of body of car, as

the width allows for the broadest gauge at present in use, and fixed or loose wheels are optional.

It would be a decided improvement and a step in advance if the cars were supplied with fixed couplings in lieu of chains; it is necessary that the fixed coupling should not in any way interfere with the present drawbar, so as to allow of the free use of shafts or hooks as at present.

The question of ball-bearings for cars is well worth considering, having already been introduced at a few collieries the writer believes with success, and any information on this point will be most acceptable.

The fact of having two different types of cars with different weights in the same colliery should be no obstacle to the introduction of a new car. The writer has had for years three different-weight cars working in the same pit, raising 1,500 tons a day, and no difficulty has arisen.

The chief object of this paper is to draw attention to the advantage of introducing a more universal design of car with a view to economy in first cost and maintenance, and in working generally. It is impossible to adopt one uniform size of car for all collieries, but two or three sizes of similar design of body of car would meet the difficulty, and a considerable advantage would be gained by so doing.

Star Mine Cars.

The mine car shown in the accompanying illustration and made by the Star Manufacturing Company, of New Lexington, Ohio, shows very strikingly the general differences in design between American mine cars and English or Welsh as illustrated in the preceding article.

The car here shown is a type very commonly used in the bituminous mines of America, but this general shape and form of construction are modified to suit the ideas of the purchaser.

In the design of a mine car the shape of the body is not so material as the construction of the truck. The wheels and axles of a car and the method of connecting them to the body determine to a great extent the life and service of the car.

It is well known that one great trouble with mine cars is the difficulty in holding the truck solid to the body. The Star Manufacturing Co. claims to overcome this difficulty by its patent truck binders. The axles are held firmly in place by means of cast brackets and wrought iron binders, so that the truck is perfectly rigid, independent of the body of the car, and by this arrangement the wheels are always in line, causing the car to run true on the track, and preventing the binding of the wheels that will always occur when the axle gets loosened from the body. A round steel axle, which passes through the brackets is used and these brackets and binders are firmly bolted to the bottom of the body, the bolts being so distributed that it is next to impossible for the truck to become loosened from the body, and if it does the wheels still remain in line with each other, so that they will still run true on the track. An oil pocket and waste keep the axle oiled and cause it to turn easily in the bracket.

Another important feature of this truck is the wheels. The self-oiling device will be found an effective oil saver. In the rear part of the hub there is a groove which catches the oil as it works back to the collar of the axle and this prevents the oil from passing out. In this groove are four holes connecting it with the oil chamber, thus furnishing oil at both ends of the spindle. On the front of the wheel is a cap with oil hole in the center, through

STAR MINE CAR.

which the wheel is oiled. This cap is held in place by three bolts and is made oil tight by means of a rubber gasket. This cap does not project out from the body of the wheel so as to be liable to be broken. This wheel is made with or without a sleeve to fit over the axle. When without sleeve the wheel turns directly on the axle. When used with sleeve, the wheel turns on

the sleeve, which is held firmly to the axle by the linch pin, and when worn on the under side can be turned over, making it as good as new. The wheels are cast in chills on the wearing surface only.

The Star Company builds these cars in any pattern of body desired, with either swing or lifting end gate. It also builds cars with the common square axle, using the same wheel, either with or without the sleeve. Where brakes are wanted the single block brake shown on cut of car is usually put on. If brake is wanted on both sides of car, a rocker bar under the car and but one lever is used. If preferred, a double block brake can be put on both sides the same as in the single block.

The Star Company will be pleased to furnish estimates on cars complete, on trucks only, on car irons, bent and punched, and on mine castings of any kind, on receipt of specifications, and will furnish blanks, conveniently arranged for filling out sizes and dimensions of what may be wanted.

The Use of Light in Mines and Factories.

Incandescent lamps are used to create artificial light to render objects visible to the eye when natural light has ceased to render them visible. The primary law of vision may be said to be in substance that objects are made visible by light rays reflected from the object to the eye of the observer; hence, we may say that the useful light given out by any source of light is that portion which strikes the object that you wish to see. For this reason, the most efficient lamp for any particular purpose is the lamp which best renders visible the objects you wish to see.

This statement scarcely admits of controversy, and the next point to be considered, therefore, is the location of the object which you wish to render visible. Conditions, of course, vary in this respect; in reading, the paper is held below the eyes, in writing the same is true, and in working at almost any kind of labor, the objects you wish to illuminate are usually below the level of the eye. It is generally known and admitted that reflected light only should reach the eyes, and hence the source of illumination should be placed so as to throw the light upon the page or object to be illuminated, but so that it will not shine directly into the eyes of the observer. These two facts being admitted, that most of the objects to be illuminated are below the line of vision, and that the source of illumination should not shine directly into the eyes of the observer, it follows naturally that the source of light should almost invariably be placed above the line of vision. About the only instance where the source of light is in line with the eye is where lamps are used for signs or signals.

Since light rays travel in straight lines, the light that strikes an object directly beneath a lamp must be emitted through the tipped end of the bulb. Therefore, the lamp that is so constructed as to give a maximum of light through its tip end, produces the greatest amount of useful light, in the sense that the term "useful" applies above.

While to the ordinary observer there is scarcely any noticeable difference in the amount of available light given by incandescent lamps, yet to those who have studied the question, there is a considerable variation in economy in the lamps of different manufacture.

The Shelby Electric Company, of Shelby, Ohio, has paid particular attention to the subject of securing the greatest amount of useful light from its lamps, and experiments carried on by scientific investigators in different parts of the country show that great

success has been attained by this company along this line. This company has developed an incandescent lamp which has peculiar advantages for the use of mines. Some of the points considered of practical value about this lamp are the following: (a) The distance between the terminal points; (b) the leading in wire is insulated in such a manner that dampness cannot effect it, consequently the life of a lamp is very much longer and the economy thus effected is very important; (c) the tip is protected by the base so that it cannot be broken; (d) the lamps are made to fit any system, any voltage, and any base; (e) the carbons do not sag, regardless of any position; (f) this lamp throws twelve and sixteen candlepower sidewise as against four to seven candlepower of some other makes. This is accomplished by the style of filament used and which is certainly most advantageous for producing useful illumination.

This lamp is built especially so as to not require the aid of white walls to add to its reflecting powers; hence the black walls of the mine are no detriment and the amount of available light for actual use is much greater than is ordinarily obtained.

In a pamphlet entitled "Lamp Efficiencies," the Shelby Company has given some very useful information, which will be sent free to any one who wishes to investigate the matter more thoroughly.

Peculiarities of Siberian Placers.

The great extent of the regions covered with auriferous alluvia in Siberia is undoubtedly the primary cause of the difficulty experienced in examining them systematically. The impenetrable virgin forests at the north, with their luxurious vegetation, fallen trees, and, above all, marshy soil, prove an obstacle to geological research. It is impossible, in the majority of cases, to follow the different strata, recognize outcrops, or ascertain the nature of the subsoil.

It was not until 1886 that the want of a school of geology at Irkutsk made itself felt, although as far back as the year 1843 the department of mines had sent Colonel Hofman to Siberia to study the gold deposits.

The information obtainable on the subject of Siberian placers is consequently scattered through a great number of monographs, and until the geological committee of the Great Siberian Railroad publishes the result of their labors, it will be difficult to treat the subject comprehensively. In contrast with the great strata of the Rocky Mountains in California and in British Columbia, which belong to the Pre-Tertiary period, as attested by the volcanic matter with which they are covered, the alluvia of Siberia belong to the Quaternary epoch and are of recent formation.

Siberian placers are situated in valleys having usually a gentle fall and often marshy. Their distinctive feature is that the pay gravel above the bed rock is covered, in the immense majority of cases, with an unproductive layer of soil.

Auriferous localities are also generally characterized by the presence of low, rounded hills testifying to the intensely destructive action of the atmospheric agents upon the rocky conformation of the country. The placers are found at a moderate altitude above sea level. In the Urals, they are met with at a height varying from 500 to 1,000 feet; in the Alatau Mountains, at 2,000 feet; in the valley of the Olekma, from 2,000 to 2,500 feet; and in the Yenisei, from 2,500 to 3,000 feet.

In addition to the native gold, frequently found in nuggets, iron pyrites, often in the form of mispickel, and all the products of its decomposition, such as magnetic oxide, limonite, hematite, etc., are met with in Siberian gravels. Copper is found, sometimes native, sometimes in the form of copper pyrites; lead has been discovered as sulphate, carbonate, phosphate, or sulphuret. Native bismuth has been found in the valley of the North Yenisei and in certain valleys of the Altai. Among hard stones, garnets, rutile, tourmaline, zircon, peroxide of tin, etc., are found.

The organic remains are most generally those of the mammoth. In 1840, it was calculated that more than 2,000 of these animals were found; some, with portions of their bodies still soft, were discovered in the frozen clays of the extreme north. The woolly rhinoceros (*Rhinoceros tichorinus*) is also frequently met with.

The state of preservation of these mammoths—animals which required abundant vegetation—indicates in a striking fashion the rapidity with which the Glacial period must have enveloped the vast plains of Siberia.

Human remains have also been found—a skull at a depth of 10 feet in the Chtogolev mine in 1860; ancient hearths; also a stone slab, with inscriptions, in a mine in the basin of the Kigas.

A feature altogether peculiar to the Siberian placers, especially those in the district of the Lena, Zeya, etc., is that the soil remains perpetually frost bound or thaws only slightly in the summer time. Near the sources of rivers places are found not frozen; these are said to be caused by warm or tepid springs beneath the surface of the earth.—U. S. Consular Report. Translation from book by Baron de Batz.

NOTES ON HYDRAULIC MINING.

Practical Points Necessary to Be Considered in Carrying Water in Ditches, Flumes, Etc.

By George H. Evans, C. E., M. E.*

There are many points in hydraulic mining on which a mine manager or superintendent should be posted.

1st. Water Facilities. Methods of measuring the average amount of water available the season through for working claims.

2d. The nature of the country through which the ditches, flumes and pipe lines have to be constructed to carry water for mining purposes, and different grades suitable for such purposes. Ditches have been constructed for long distances with too heavy a grade and so the water acquired too much velocity and completely washed away the greater portion of the ditch. Again ditches have been constructed with too little grade, and cases have occurred where ditches have been made with the fall in the wrong direction.

3rd. The quantity of water different size pipes will carry or that can be discharged through pipes and nozzles under various heads.

4th. The friction caused by using pipes of too small diameter, and loss of head due to this, also loss of head due to bends of short radius and angles of all kinds in pipe lines.

5th. A knowledge of the different motors used in connection with hydraulic mining and of the various kinds of water wheels.

6th. Strength of material, chains, hemp, manilla, wire ropes.

7th. Bursting and working strain of iron and steel pipes of different diameters. Strength of iron and steel plates, single and double rivetted with punched and drilled holes.

8th. Methods of economically treating alluvial deposits in large quantities when there is not sufficient grade for ground sluices, and yet enough for piping or in cases where, owing to the law, it is necessary to impound the tailings.

Water Facilities. Great care should be taken in arriving at the average quantity of water available all the year or during the entire season, so that sluicing can be carried on continuously. To do this creeks or streams must be measured at different points to approximate the average supply of water that can safely be relied on from such source, allowance being made for evaporation and leakage which in cases reaches 20 per cent. A simple method of measuring the quantity of water flowing in a stream is as follows: Measure depth of water in feet at 6 to 12 points across stream at equal distances, do this in two or three places along a fairly straight course, add all depths together, divide result by number of measurements taken. This will give the average depth of stream and such depth multiplied by average width in feet, will give its cross section or area in square feet, which multiplied by the velocity of water in feet per minute gives the number of cubic feet flowing per minute in the stream.

To find velocity, step or measure off 120 feet along the bank, and to allow for surface of water flowing faster than bottom or sides and thus obtain mean velocity, call the measurement 100 feet and at the commencement of this 100 feet throw into the middle of the stream pieces of paper at intervals and note the time

it takes each to reach the end of the measured line. Then divide the total time in minutes taken by all the floats by the number of floats, and the result will be the average time taken for each float to make the trip. Divide average time in minutes by distance in feet, viz.: 100, and result will be velocity in feet per minute, and this multiplied by the area in square feet will give the number of cubic feet flowing per minute, or if the answer be required in miners' inches, multiply the cubic feet per minute by 2 and divide by 3.

Nature of Country for Grades.—This must be considered in connection with ditches or flumes in order to establish the correct grade upon which depends the velocity or destroying force of the water, and in locating the sites for water races.

1st. Ascertain by aneroid the lowest point in stream or water supply that will allow sufficient grade for conveying the water to a point suitable for working claims, and if the maximum supply obtainable is less than required for advantageous working, then favorable sites must be located for construction of storage dams or reservoirs capable of storing sufficient to keep up the required supply.

2nd. Should the lowest point in the stream contain more than enough to meet the requirements of the mine or mines in driest season, then the locator should select the greatest elevation that the country through which the ditch has to be constructed, and the water supply available at driest season will allow, so that the ditch when completed will command the largest area of mining ground, with the maximum head of pressure. Ditches have been

constructed to command large tracts of mining ground and found to have tapped the source of supply at such an elevation that it was impossible except in the wet season to get sufficient to work with.

3rd. All timber line along the ditch should be curtailed and when fluming cannot be avoided, iron or steel should be considered for permanent ditches, the durability and great saving in cost of maintaining, more than compensates the owner of the ditch. In case of necessary timber work, the most durable should be chosen and coated with asphaltum or mineral paint.

4th. Line of ditch should be laid out as short as possible and in coming around long points or in places where sidelings are very

steep and of loose rocks tunneling through spurs should be considered, or when tunnels can be constructed without timbering they should be preferred to long ditches around such spurs or points unless ground for ditching is exceedingly good and extra distance quite short.

5th. Along the line of ditch, springs or water courses should be connected by means of short flumes or ditches that the loss of leaks and evaporation from main supply will be entirely or partly made up. By-washes or water gates should be constructed in case of sudden increase of water from rains or melting snow.

At different points along line of races where fluming is necessary allowance should be made for an increase of grade in order that the flume can be constructed of much smaller dimensions than the ditch and yet carry all the water required. The least amount of friction in ditches and flumes is developed when the least wetted border is obtained, and to do this the width of the bottom must be from $1\frac{1}{2}$ to $2\frac{1}{2}$ times the depth of the sides.

In constructing tunnels when they will stand without timbers the Gothic arch is best, as it stands better than the circular, or any other kind of roof and does not flake. Tunnels constructed with circular roof have flaked off naturally till they have assumed the section of a Gothic arch.

EXAMPLE OF SLUICES, CALIFORNIA.

*These notes will be found very much amplified in the author's work entitled "Practical Notes on Hydraulic Mining," published by John Taylor & Co., San Francisco, Cal.

Grades and Capacity.—The character of the ground through which a ditch is made bears on the grade required. In ordinary ground water should travel at rate of 180 to 200 feet per minute. The grade then will be determined by dimensions of ditch and its intended carrying capacity.

Races through which water flows at too high a velocity through ground of a porous nature will never be free from leakage, because the velocity of the water will not allow sediment to settle, and sediment traveling with water at moderate speed is relied on to tighten up portions of the ditch cut through ground of a porous nature, and again if velocity is too high it scores holes in the bottom and sides of ditch when constructed in sandy or clay soils. When owing to weak banks it is necessary to build walls on the lower side of a ditch, the ground should be removed to obtain a solid foundation and two walls an outer and inner, should be built up with space enough between to allow a good puddle clay to be rammed in, such a wall if properly constructed will never give further trouble.

All earth, trees, roots, must be moved quite clear of the lower side of the ditch with the exception of just sufficient to make a track, otherwise slides are apt to occur.

At entrance of tunnels and commencement of flumes and at points where velocity of water is retarded the effects of water changing its form at such places must not be neglected.

To find area of section of flume or ditch with straight sides, multiply width of bottom in inches by height of sides in inches. The product will be area in square inches and this divided by 144 gives area in square feet.

Carrying Capacity of Pipes. Discharge of Nozzles, etc.—Pipes

EXAMPLE OF SLUICES, BRECKENRIDGE, COLO.

and nozzles are of great importance. The pressure of water is only as the head without regard to size of pipe. A pipe line of 6 in. pipe and another line of 40 in. pipe with same fall or head will both give the same pressure. Miners have been known to ask if the pressure could not be doubled by doubling the diameter of the pipe.

The principle of hydrostatics in building storage dams and reservoirs should be understood, remembering that there is the same pressure on the bank of a reservoir with water three feet deep and extending back for a distance of 10 feet as there would be if the water dammed back 10 miles, so long as the depth remains the same.

Nozzles require great care in construction, to be correct of form in order that water leaving them will be in solid stream instead of scattering and thus losing its power which is the case with nozzles of improper construction. To get the best effect it is necessary that the head of the pipe conveying the water should be three or four feet under water to prevent air getting into the pipe causing water to scatter when leaving the nozzle.

Water issuing from a nozzle should attain the height of the head. A nozzle with 300 feet head should throw a stream a height of 300 feet, this however, cannot be attained in practice owing to the resistance of the air.

All pipe lines should be laid as straight as possible or with curves having as large a radius as can be obtained, and new pipes well coated will carry more water than old pipes rusted inside. Allowance must be made accordingly. It is well to allow $\frac{1}{4}$ diameter of pipes under 6 inches and 1 inch on all diameters over 6 inches.

First the fall available for the pipe line must be ascertained

and its length in feet. Knowing this and the quantity of water that is to be used, it is easy to determine the diameter of pipe. Water should flow in pipe at velocity of not more than 3 feet per second.

Friction in Pipes.—When large quantities of water are discharged from pipes of small diameter the pressure is greatly reduced. Errors are made in bringing water supply to claims and laying down pipes of too small diameter, thus reducing the effective head or pressure to less than one-half that available with pipe lines properly constructed.

Water flowing through pipes should not exceed 3 feet per second or 180 feet per minute, and if users of water for hydraulic purposes had their pipes of the correct diameter to insure velocity not exceeding that named above, there would be little trouble. The friction of water in pipes increases as the square of the velocity and depends on the condition of the pipes, whether they are foul and rusty, new, or in good condition. Even the rivet heads in a pipe line of considerable length cause a good deal of friction and loss of head. Loss of head is also due to bends and angles. This is sometimes great owing to the number of sharp bends or changes in the direction of a pipe line. In a pipe line there should be no bends having a radius of less than five diameters.

Considerable space is given by Mr. Evans to strength of material which we must omit here for lack of room and turn to methods of treating alluvial deposits in large quantities where sufficient fall is not available, sluices, grades, etc.

Grades and Sizes of Sluices.—A wide sluice will carry more material and save more gold with considerably less grade than a narrow and deep one.

In gold saving there should be as thin a film of water and material in the sluices as possible. There must be just sufficient water, however, to cover the largest stones sent down the sluice.

As to the grade of sluices, with a grade of 1 in 20 to 1 in 25, 40 miners' inches or 60 cubic feet per minute will wash from 140 to 170 cubic yards per day of twenty-four hours, and with light grades the depth of water in sluices must be as shallow as possible, just so that it will move the largest stones and prevent the sand from packing.

When there is a large proportion of heavy stones the best results are obtained by having about 10 to 12 inches of depth of water in the sluice, assuming that the large stones are not over 10 to 12 inches diameter.

Rank of Coal-Producing States in 1899.

The amount and value of product, and percentage of each State is given as follows by Mr. E. W. Parker.

1899.

THE GREAT LONDON FAULT

Of the Mosquito Range and the London Mine—An Illustration of the Evolution of a Fault.

Written for MINES AND MINERALS, by Prof. Arthur Lakes.

All miners both coal miners and metal miners are interested in faults, often painfully so.

We have lately in the Mosquito Range, South Park, Colorado, had an opportunity of seeing in a remarkable and picturesque way a great fault in all its phases of evolution. We have also met it as an important factor in a noted gold and silver mine of that region. The fault in question is called the London Mine fault, because it passes in close proximity to the London Mine on London Hill, between North and South Mosquito ranges. The fault cleaves the Mosquito Range, which lies between South Park

faults resulting from lateral or tangential pressure at right angles to the axis of the range. The range is folded up like sheets of paper or cloth. Beginning on the south we find the great steep fold of Sheep Mt. which mountain owes its shape to its folded structure. On the steep face of Four Mile Cañon the whole anatomy of the mountain is clearly shown and the steep arch appears in all its ideal symmetry and perfection. Granite forms the base of the mountain, and over this bends the arch consisting of Cambrian quartzites below, with Silurian and Carboniferous quartzites above, with a sheet of white porphyry capping the summit.

The course of the fault is shown in the profile of each mountain by the deep notch it makes in its outline. This is seen here between Sheep Mountain and Lamb Mountain west of it. The latter mountain is capped by a heavy bed of porphyry, the rest of Lamb Mountain is composed of Weber grits of the Middle Carboniferous, relics of which are found on the top of Sheep Mountain, showing that they have slipped down in Lamb Mountain over 1,000 feet, the amount of slip is about 2,000 feet.

Some of the strata of the S fold are thrown up on edge at point B on Lamb Mountain near the fault. Here and in each cañon where the fault is known to exist, the exact fault line or line of fissure is entirely obscured as is commonly the case with great faults by fallen masses of debris. The zone of the fault line is also characterized by a good deal of coloring matter of iron oxide. Nature it would seem likes to conceal her faults. It is only in mines or where the debris or vegetation is removed or washed away clean by the action of the sea or some other body of living water that we can get a chance of seeing the exact line of the fault fissure. The next most striking appearance of the

fold and fault as we follow it north from cañon to cañon is in Sacramento cañon. There we observe another symmetrical arch, but flatter than that of Sheep Mountain, though on its west side it bends down quite as vertically towards the fault line. On the west side the lines of folding and bending down towards the fault are beautifully shown in graceful lines of curvature among the turf-covered rocks.

and Leadville, from end to end for a distance of some twenty-five to thirty or more miles.

The Mosquito Range consists of a series of Paleozoic quartzites, limestones and intrusive sheets of porphyry, folded and faulted. These strata, forming the floor of the basin of South Park, are folded up on the west into the Mosquito Range, which like a breaking wave, overhangs one side of the great Valley of the Arkansas, in which Leadville is situated. On the east side the strata rises gradually into a lofty arch or anticlinal fold of at times wonderfully perfect and symmetrical shape underlain by granite. This S fold on reaching too severe a strain of tension broke down into the London fault. The same compressive movement that seems to have been laterally squeezing the strata up against the unyielding mass of the Sawatch Range west of it caused also other minor folds, which similarly broke down into faults with out in many cases showing any sign of the arch or fold, from which they broke, not any sign of a fault scarp or cliff. All these signs have been removed by erosion except in the case of the London fault, where the fold that preceded the faulting is beautifully shown on the walls of each successive cañon cutting the range. The accompanying diagrams will show the wonderful symmetry of these arches, often as perfect as those of masonry. Owing to these successive step faults we descend to Leadville on the west side of the Mosquito Range by a series of gigantic steps.

In the North Mosquito amphitheater, near the York mine, appears to be the relic of a fault scarp or cliff such as is not often seen in faulted ground, such cliffs or scarps being generally removed by erosion. The fault shows in a remarkable manner how folds by extreme tension snap and pass into faults. To the south the folding and faulting die out in a rounded hill, known as "Round Mt." To the north the dying out of the fault is not known; by some it is said to extend as far as the mining district of Kokomo which would make the extent or length of the fault fracture upwards of 50 miles.

The Mosquito Range is also a typical example of how certain mountain ranges are formed by simple or complicated folds and

FIG. 1.—THE LONDON FOLD AND FAULT ON SHEEP MT., FOUR MILE CANON.

FIG. 2.—THE SACRAMENTO ARCH AND LONDON FAULT, SACRAMENTO CANON.

FIG. 3.—LONDON FAULT ON SOUTH FACE OF PENNSYLVANIA HILL.

In the next cañon of Big Sacramento we lose all signs of the arched structure. We can only recognize the evidence of a great fault by Cambrian quartzite resting on granite forming one side, and terraced lines of outcrop of Middle Carboniferous Weber grits forming the other or west side with a huge swath between them of gaily colored debris obscuring yet indicating the general line of the fault fissure. The fault is somewhat similarly shown on Pennsylvania Hill. At the top of the hill, presumably near or close to the fault line, a prominent knob occurs of quartzite which has been highly colored by iron oxide and shows on its east face a complete metamorphism into cavernous quartz.

From Pennsylvania Hill we cross the next gulch to London Hill, where the celebrated London Mine is located in close proximity to the line of fault. The general direction of the fault is N. 15° W. to N. 45° W. The line is not quite straight, its average may be N. 30° W. or N. W. magnetic. The great S fold everywhere close to the fault has the same direction. The fault cuts this fold, now in one part, now in another, west of the anticlinal axis.

We now approach London Hill itself from the south, and we observe that this hill consists of two parts, one of solid granite on the east with stratified Paleozoic rocks on the west, the division is caused by the London fault which cleaves the hill in a general N.W.-S.E. direction. The line of the fault on the south side is only shown by the broad swath of detritus between the two formations of the stratified rocks and the massive granite; on the opposite or North side of the hill the division is somewhat more clearly shown. It is on this side at the base of the hill that the London Mine is located.

The Paleozoic strata dip easterly towards the fault on London Mountain at an angle of about 25 degrees, but when they approach the fault line they appear to be hurled backward from it and dip towards it at a steep angle of some 50°, the limestones and quartzites standing off shining in the sun like metal plates. It seems probable that the fault fissure between the sedimentaries and the granite may be here filled with a body of quartz as such appears at the top of the hill, though it is possible that this, as at the knob on Pennsylvania Hill may be only a highly metamorphosed quartzite instead of a true vein filling of a fissure. Whether or not the fissure itself is mineralized remains to be proven by later development.

In the mine the ore bodies lie in what appear to be fissures in a porphyry sheet, in some places they are ordinary contacts between limestone, shale or quartzite and porphyry. Wherever the strata have been pierced, or along the walls of the veins, evidences of intense slipping or shearing movements are apparent; the walls are polished by this movement, and pieces of black shale shine like plates of steel. The movement appears to have been like that of violently folding up a roll of paper or the sheets of an unbound book, the several sheets slipping upon and polishing one another and producing slipping fissures between them. Such

COAL FIELDS OF THE PHILIPPINES.

Facts in Regard to Their Location, Extent, Quality of the Coal, and the Opportunities for Profitable Operation.

By Mr. G. D. Rice*.

Since the practical conclusion of hostilities in the Philippine Islands there has been a great deal of prospecting done by representatives of American mining companies, individual miners, discharged soldiers of the army, and even the natives, with the result that all sorts of mineral deposits, including coal of a good quality, have been located and in some instances worked successfully. Your correspondent has recently returned from a trip to Cebu, Negros and Bataan. The finest beds of coal thus far developed are in the island of Bataan, where they extend over a large territory. Since the establishment of the mining bureau at Manila, by which mining papers are cleared and titles to lands sought out and adjusted, there has been a great movement towards the establishment of plants for the operating of the coal mines in the southern section of the Philippines. There are capitalists represented in the enterprises who control large and successful mines in the United States and other countries, and the indications are that within the year there will be important steps made in the working of the mines of the Philippines. In most cases the coal mines have been discovered by the miners who were prospecting for gold, silver, lead, copper or other valuable deposits, which are known to exist in Luzon, Panay, Negros, Mindanao, Gimeras, Bataan and Cebu. On Gimeras there are several mines in operation, but the coal mine there has not been developed to any important extent. On Panay, the coal mines are still in their infancy, and such specimens of coal as have been brought to notice are not

FIG. 4.—THE LONDON MINE.

fissures in the porphyry sheets have been filled with quartz veins carrying gold and silver-bearing ores. These veins are from a few inches to two or three feet wide, the ore consists of pyrite with some zinc and galena all containing more or less gold. The ore occurs in chutes at intervals with more or less valueless ground between. There are two veins which after a time merge or come together into one vein.

From want of accurate knowledge of the geology of the hill, it was supposed that these slip fissures might continue down into the granite below and a long cross-cut tunnel was contemplated to cut them at great depth down in the granite. We do not think these slips so continue but rather that they are confined to the sedimentary zone and its included porphyry sheets and that they conform to the bedding planes of the strata. The only thing that would be encountered by a cross-cut in the granite would be the fissures of the Great London Fault and whether or not this is mineralized is a matter at present for conjecture only.

Exploration for fresh veins or ore bodies or ore-bearing strata must be confined to cross-cuts and winzes in the sedimentary zone alone and particularly at contact with intrusive sheets of porphyry.

Effect of Locating Across the Vein.—Where by mistake a mining claim is located across, instead of along, the vein passing through the location point, the rights of the locator are governed by the facts as they exist with regard to such vein. His side lines, as located, become end lines, and he is not entitled to any extralateral rights thereunder, although another vein, extending transversely to the one intended to be located, may have apex inside of such surface lines.—*Cosmopolitan Min. Co. v. Foote et al.*, 101 Fed. Rep. (U. S.) 518.

of so good a grade as found in the beds of Bataan, Cebu and Negros. Mindanao is an extensive field for the operations of miners, and about the first thing that a new party of miners do when they arrive in the Philippines is to strike out for this island. The miners who have gone to Mindanao usually discover some sort of a mine, for there have been already established there mines for getting coal, iron, gold, silver, lead, copper and other metals.

Coal Mines are Extensive.—According to information secured from the mining bureau, from a number of miners who have prospected for coal, and from personal observation, the coal mines of the Philippines are practically the most extensive of any mineral. The geographical formation of the islands renders it difficult to locate the leads and follow them, but in cases where the prospectors have been successful, the results have proven very encouraging. In nearly all of the places which I visited it seems as if serious eruptions of the earth must have occurred some time in the past, and the results of these eruptions handicap mining. The volcanic eruptions of centuries ago evidently broke and separated the leads of coal, and the result is that, although the leads often extend over large territory, they frequently break abruptly, and one would suppose that that was the end of the lead. But if he follows the earth a short distance, he will locate the lead again. The eruptions seemed to have broken the leads all through the islands, with a resulting series of short leads.

Tracing the Leads.—But the miners have no trouble in tracing the general direction of these extensive leads. I have been with working parties who have followed the leads from one side of an island to the other without losing the general trend. When a lead stops, the other end, separated by volcanic eruptions, is

* From the American Gas Light Journal.

usually located shortly after. It would seem as if two great belts of coal extended through the archipelago at an angle of about 60° southwest and northeast. The interested parties are buying up considerable of the property in the vicinity of these belts with a view of working the same. The operations, however, are chiefly confined to the islands of Bataan, Cebu and Negros. Hardly anything has as yet been done in Luzon, Panay or other islands, beyond the preliminary preparations. The largest deposits of coal are evidently in the islands of Cebu and Negros, while Bataan has the reputation of having not only extensive beds but a fine grade of coal. From specimens furnished and subjected to the usual tests, the coal is of Tertiary age and a highly carbonized lignite.

Mines Worked Since 1827.—Mining is no new idea in the Philippines. The natives have been getting out coal and using it since 1827. The mining has been done on a small scale, and no works of any sort have been established, because the ladrones and freebooters of the mountains would have destroyed or looted any equipment put up. The mining of coal in the past, like all other mining in the Philippines, has been conducted with the crudest types of instruments, often the miners being supplied only with bamboo bars and wood scoops for shovels. At one place inspected by the writer, where even now they are working a native mine as of old, they did not have a single metal tool. Most of the work seemed to be done by hand. I saw natives use their hands to scoop up earth. They had little hammers made by entwining sharp pointed stones to the end of a stick, and these hammers served as picks and to break off pieces of the coal. This coal has been sold to water craft plying with mails and freight between the islands. It seems that the first coal mines were worked on the island of Cebu, and it is only recently that the better grades of coal on the islands of Bataan have been used. For many years the operations at the coal mines have been very irregular. Sometimes the mines would be operated full blast for a year and then remain idle for a same period. The natives are not inclined to work at mining or at any other operation, unless compelled to for need of money and food. It is only when driven to it that they will get out their tools and go to work. Therefore the best of mines have frequently been shut down for stated periods from this one cause, and, as is well known, it is very unsatisfactory to operate any kind of mines on this plan. I recollect in one instance where they stopped work, the mines flooded and considerable expense was entailed in getting the mine back into a paying order.

The Mine of Uling-Uling.—One of the chief mines of the Philippines is known commercially as "Uling-Uling," and it is located on the island of Cebu. The coal from this mine is said to be better in quality than either the Australian or the Shanghai coals, which are landed here for sale to the steamers and to the manufacturers of the islands who use steam power. The cost of the local coal, as compared to the cost of the imported, is, of course, much lower; yet the bad management of the mine mentioned above, such as shutting down for a period when the coal is most wanted, compels the users of coal to depend upon the dealers who handle the foreign coals, for the reason that the latter coals may always be found in stock and ready for delivery.

Future Prospects of Philippine Mines.—It is very evident that if the Americans had never taken possession of the islands the coal mines would be useless to the country. The few thousands of tons of coals taken from the mines each year were hardly sufficient in importance to cut any figure in the commercial transactions of the islands. There are a great many manufacturing industries distributed over the islands, all of which have been compelled to use wood, cane and other materials under the boilers of the steam plants because of inability to secure coal. These industries include mainly the sugar mills, of which there are dozens in every square mile, all using a boiler to operate the cane crushing machines and to raise the necessary steam for heating liquids, etc. In crossing the islands with a military expedition recently it seemed to me that we met with one of these isolated sugar mills at the rate of two and three in every mile on a straight line. There are a great many woodworking plants springing up under American control, and the owners inform me that, although wood fuel is available, they would prefer coal, if the latter can be obtained at proper prices and without trouble. Then there is considerable shipping touching at all of the principal points in the islands, all of which calls for coal for fuel purposes, and as the local mines have thus far been unable to keep the coal yards filled with coal, such coal as there is on hand is imported, and imported coal is very costly. It is sold in sacks, and the sacks are handled as if they contained precious metals.

There are railroads coming into existence in the islands, and the locomotives have to be changed over for burning wood because of lack of proper supplies of coal. It is just the same in the metal working industries. The steam plants were previously intended

to burn coal, but the latter not being obtainable, except at intervals, the proprietors find it best to have the furnaces changed for using wood. There is plenty of wood in the islands, but it is not of course satisfactory for service in all cases of steam raising.

For Gas Works.—There is no doubt if coal could be mined in proper quantities gas works would be established in the islands, for the reason that the expense of oils for illuminating purposes in the Philippines is exceedingly high. Oils for lamps are six times greater in cost than in America. By the time that the oils get transported to the interior, the cost per gallon is so high that only the rich can afford to have a light. I have seen whole barrios of people go to sleep shortly after dark because of not being able to afford a light. Now if it were possible to secure a sufficient supply of coal, there is little doubt that some of the enterprising Americans, who are here at the present time for the special purpose of introducing up-to-date ideas, would undertake to establish gas works. A gas works would pay handsome profits under the circumstances. The coal consumption would be considerable and the mining business assisted.

Coal Tar in Demand.—This is a great country for using vast quantities of coal tar. If gas works were established the consumption of tar in the islands is so great that the proprietors of the gas works would find themselves making considerable money from the sale of the coal tar. The reason for the call for coal tar is that much of the house building in the Philippines is done by means of split bamboo, and the tar is used to fill in the crevices. Then the shipping is usually built up by means of plaited work in split bamboo, the keel and lower portion of the native craft being solid wood, cut from a tree, while the sides are of this bamboo plaited work, in which the meshes are liberally filled with tar. The coal tar is at present shipped from England, Japan and Russia, and by the time it gets here it is costly. There are practically no paints available, so that the tar is often used as a paint on nipa huts and bamboo houses, for the reason that it makes a good coating and the tar keeps the vermin away. But the cost of the tar prevents its general use. If gas works were established, and the coal tar sold at reasonable rates, the market for it would be very large.

As to Roads.—Of course one of the leading features of mining in the Philippines is the condition of the roads. Your correspondent has been on the go for a year in these islands, and has traversed the roads of nearly all of the southern islands several times over, and found them to be uniformly bad in the wet season and only passable in the dry season. The American soldiers are doing wonders with the roads, however, as wherever the soldiers have established garrisons, they have made it their business to turn out the natives and compel them to grade the roads for miles in all directions. Then the bridges are nearly all down, the insurgents having burned many of them, but by the time this letter reaches the United States, the bridges will in most cases have been replaced; for the department commanders throughout the Philippines have ordered that district commanders see to it that all bridges within their district are rebuilt and the roads made passable for both the wet and dry seasons. The natives are called upon for this work, and hundreds of them are working at each of the crossings rebuilding the bridges. Transportation of the coal to the sea coast or to the markets of the interior can, therefore, be accomplished with practically little more difficulty than under ordinary circumstances in any country. In some of the mines now in operation they are getting the coal to the markets on pack animals, and these animals carry quite a load. In some places they use the caribou and the drag sled. This is the best way whenever the trails through the hills are wide enough for passage. If the trails are narrow, then only pack animals can be used, but even this mode does not overcome the narrow paths around some of the mountains. On one occasion I saw a pack horse go over the sides because the bag of coal on the inner side struck the wall of the mountain to the side of the path, causing the horse to lose his balance and go over the side.

Labor.—The cost of labor in this country is so exceedingly small that many of the defects of transportation and machinery are overcome.

The native laborers can be hired for 10 cents per day to work in the mines, and the only sort of shelter they need is a bamboo shack. They will expect to be provided with rice and tuba, costing about 3 cents per day for each man. Coolies can be secured at even a lower rate per day, one new mining company paying only 8 cents per day, and furnishing lodging and food for its laborers. There are plenty of men to work at this price, for the wars are practically over and the soldiery must go to work at something. Then there are the caribou and the native horses to use for purposes of transporting the products of the mine to the coast. These may be purchased outright for about \$6 gold each, or can be hired at the rate of about 10 cents per day each. The hours of working are from 6 A. M. to noon, when a two hours' rest is taken, and work is then resumed to 6 P. M.

Titles.—Many miners who have undertaken to develop coal and other mines in the Philippines have made the serious mistake of investing their capital in claims not properly adjusted. A year ago it was the custom for prospectors to settle down on any piece of mining property and hold it by force. They often had to shoot interfering natives, and trouble resulted sometimes in the natives forming, and as a result of the uprising, unless United States troops were near, the miners have been killed. I recollect of several parties attacked in this way. The best method is to first locate the property, and when it is assured that it is worth the working, a visit should be made to the Mining Bureau at Manila, which is controlled and officered by the Government, where the whole history of the property, as recorded by old Spanish land grants, may be secured. All papers relating to lands of all kinds are on record at this office, and when this office assures a miner that such and such a property is free for him to operate upon, or can be purchased from original owners at a stated price, then the miners can return to the lands, establish their rights and no one can interfere. But this habit of settling upon a piece of property, even when the native owner lives within sight in his shack, is a risky piece of business. The natives know no value in their land until they see Americans settle upon it, and begin to take out marketable products. Then they want to drive the prospectors off and work the mines themselves. Bloodshed invariably results, for the reason that, even if the native sells for a small sum of money, some other relative of the native or another claimant of the property will appear. But if the proper papers are secured from the bureau at Manila, the responsibility of ownership rests there, and the miner can refer the native to that office.

THE FIRST-AID PACKET

In Civil Practice and the Organization of First-Aid Societies. Their Value in Mining Regions.

By M. J. Shields, M. D., Jermyn, Pa., Attending Surgeon to the Carbondale Emergency Hospital.*

My object in writing this article is to call the attention of the profession, especially those physicians residing in mining regions and those who practice in manufacturing and railroad centres, to the value of the first-aid packet and also to the good that can be accomplished by the organization of first-aid societies in districts where their clientele are engaged in such hazardous occupations as mining, railroading, and iron working.

The idea is not original with me, for such societies have existed in England for a number of years under the name of the St. John Ambulance Association, which has for its president no less a personage than His Royal Highness the Prince of Wales, and among its other officers eminent men in all walks of life.

I have practiced during the whole of my professional career in the coal-mining regions of northeastern Pennsylvania, where we have a great many men who come from the mining districts of Great Britain, and in conversations with them the subject was first brought to my attention. We all know what serious results oftentimes follow mining accidents in the form of sepsis, loss of blood, tardy recovery, and sometimes permanent disability, all resulting from the filthy condition in which the surgeon finds the wounds and injuries and the time that elapses from the occurrence of the accident until the doctor gets to his patient, for these accidents (in mining) occur sometimes a great distance underground and sometimes several miles from the sufferer's home or the district hospital.

Then, also, the poor sufferer fares quite badly in the hands of his fellow-workmen, who all get excited in trying to aid, and oftentimes do the injured man more harm than good. Several instances have come to my knowledge in which miners who were trying to extricate an injured man from under a fall of coal have lost their heads and either walked or stood on top of the pile of coal that was pinning the poor fellow down, thereby adding several hundred pounds to the weight that was on top of him, and when he was finally got out he was handled sometimes roughly, owing to the excitement or lack of training of his brother-workmen. So, knowing all these things and believing that if an organization on the same plan as that of the St. John Ambulance Association could be started, I was sure it would be the means of doing much good to suffering humanity and would be of great benefit to the surgeon who attended these cases by securing cleanliness of the wounds, less shock from loss of blood, etc.

Accordingly, about February 1, 1900, I organized a society consisting of twenty-five men, all working in one colliery. This colliery employs about 400 men and has five headings, or main

gangways. These twenty-five men are divided into squads of five, and one squad is distributed along each gangway of the mine. One of the five is chief of the squad and is selected after passing an examination on the topics pertaining to the first aid to the injured. In his keeping is a small box containing cotton, a rubber tourniquet, flexible splints, a bottle of olive oil and lime water, a bottle of aromatic spirit of ammonia, a small glass, and a spoon. There is also a folding stretcher kept in each gangway, and each member of the squad is provided with a first-aid packet, which he carries with him.

The society meets twice a month, and at each meeting some other physician or myself gives short talks on the subject of first aid. Each member has a little book called *First Aid to the Injured*, written by the late Dr. Peter Shepard, surgeon-major, British Army, which is published in London by the St. John Ambulance Association, and contains in its hundred pages about all that is needed for the average working man. I have them study this book, which contains some anatomy, a little physiology, some information about bandaging, and instructions as to how to care for injured persons till medical aid arrives. It also contains rules for resuscitating persons whose breathing has become feeble or ceased, in cases of hanging, drowning, poisoning from opium or gas, and electric shock. The book also gives a stretcher drill and full directions as to lifting and carrying an injured person. I could not find anything published in this country that suited my purpose, in point of brevity and cheapness, as this work does, which costs only thirty cents delivered in the United States. Of course, there are several excellent works written and published in this country; the one by Dr. Doty is an excellent one, but it is too extensive and the cost too much (\$1.50) for the average miner.

As regards the financial affairs of this society and the means of raising money for the purchase of material, first-aid packets, etc., in every mining and manufacturing district, as is well known, there are a number of accident and benefit societies which pay their members so much a week in case of accident, and they can be made to understand that such an organization is the means of getting its members who are injured back at work sooner than would otherwise be the case, which means a saving of money to the benevolent society or lodge.

Now, in my town, we have a number of such organizations, and they have all contributed to the first aid in both men and money, and the miners have as individuals contributed a small sum, I think ten cents each. As we are equipped now with forty-eight first-aid packets, tourniquets, splints, stretchers, and books, the total cost of which has only been \$50.00, we have not yet asked the mining companies for any financial assistance, but I have no doubt that if we needed it and the matter was put before them they would willingly contribute to such a cause.

As I stated in the beginning, my sole purpose in writing this article is to bring this matter before the physicians who are living in districts where men, from their occupation, are unusually liable to accidents; and, as we are or should be in this progressive age interested in preventive medicine and surgery, I think this matter is worthy of much consideration and I have not the least doubt that whoever once takes the initiative will have the zealous and hearty cooperation of his patrons and the public. In my case the men whom I have organized have entered the work with zeal and are faithful in trying to learn how to aid their fellow-workers, giving their time and money to aid their unfortunate collaborators.

In closing, I should like to state that the physician who organizes a first-aid society should carefully select his men; they should be of temperate habits; men who are intelligent and conscientious, men who will be faithful and punctual in attending the meetings of the society, and men who understand that they are doing this for sweet charity's sake, that do not get disconcerted easily, and have no aversion to the sight of blood. In our organization I had to weed out several who could not stand the sight of blood or of an injured person.

Physicians who have practiced any length of time in a community soon get to know who is capable of helping in accidents, and these are the men to be selected. Then, again, there is no need to provide every man who works in the rolling mill, factory, or mine with a first-aid packet, because the men usually work together and some one who belongs to the society is almost always present or not far away and can be almost instantly in attendance.

These classes or societies can follow a prescribed course for a year or so, and then a certain number of the most proficient should pass an examination and be given a certificate. Then new members could be brought in, and if there were several societies in the vicinity interest should be kept up by competitive stretcher drills, trials of skill in bandaging, etc. I should also recommend that the members of such societies wear a badge or boutonniere of some suitable design, so that they could be easily found in case of accident.

* New York Medical Journal, Sept. 8, 1900.

THE ELECTRIC MINE LOCOMOTIVE.

Its Development as Illustrated by a Comparison of One Built in 1889 With Those Now in Use.

A comparison of the modern electric locomotive with its prototype of a few years ago shows in a striking manner the rapid

FIG. 1.—H. M. 80. MINE LOCOMOTIVE. INSTALLED IN 1889. STILL IN USE.

advance of modern engineering. The electric mine locomotive has long since passed the experimental stage, and, by years of successful service, has clearly demonstrated its superiority, under ordinary conditions, as compared with rope haulage and compressed air or steam mine locomotives. It must be admitted, however, that the various rope haulage systems possess important advantages on severe grades of any considerable length. One of the earliest types of the electric mine locomotive is shown in Fig. 1. This locomotive is a veritable pioneer and was built in 1889 by the Thomson-Houston Electric Company for the Erie Colliery of the Hillside Coal & Iron Company near Scranton, Pa. A locomotive known as the "Terrapin Back," was built by the same Company in 1891 and several of these machines have operated continuously up to the present time and doubtless still have a long future of usefulness.

The locomotive illustrated in Fig. 2 is the most modern type and is the result of a process of evolution, of continual change and improvement. The contrast between the locomotives shown in Figs. 1 and 2 is very striking and shows the marvelous development that has been made in the design of electric locomotives within a very few years. In the design of this locomotive the following important requirements have been constantly kept in view: 1. Reliability and convenience of operation. 2. Easy access to all parts for examination and renewal. 3. Ease and perfection of control. 4. Economy of current consumption. 5. Large momentary over-load capacity. 6. Immunity from injury due to derailment, fall of roof or other accidents common in mines.

It may be of interest to point out some of the salient features of modern mine locomotive practice. The motors form the most important part of the locomotive and should be thoroughly waterproof and of ample capacity. The locomotives manufactured by the General Electric Company are equipped with standard street railway motors which represent many years of

experience in the field of electric traction. The same remarks apply to the controller, which is of the well known magnetic blow-out type, to whose excellence is due, to a great extent, the remarkable development of the electric street railway. This type of controller may be found the world over and is a very important feature of a mine locomotive, which operates under the most severe conditions. The superiority of this controller is due to the magnetic blow-out which automatically extinguishes the arcs at the contact fingers, and without this feature it is doubtful if the mileage of the electric street railways in the United States alone would have, at the present time reached the marvelous aggregate of 20,000 miles.

The standard mine locomotive manufactured by the General Electric Company consists of two heavy side frames and two end frames of cast iron, accurately machined at the joints and held together by heavy bolts. The weight of the locomotive is supported by the axle boxes through heavy double coiled springs. The motors are mounted on the axles, which are driven through the medium of a gear and pinion with machine cut teeth running in a gear case partially filled with oil. As the motors are spring suspended from the side frames, the axles carry directly only a portion of their weight, and the jars and strains due to rough tracks, are reduced to a minimum. At one end of the locomotive is collected the operating apparatus including the controller, brake stand and sand levers. Special attention has been directed to the brake mechanism, covered by letters patent, by means of which the operator may skid the wheels on a dry track with a very slight muscular exertion. It is unnecessary to tug and strain at the brake wheel to effect a stop, and, due to the absence of all pawls and ratchets, the brake will remain indefinitely in any position in which it may be left by the operator.

The arrangement of the brake mechanism is such that the wear of the brake shoes is automatically "taken up," a feature of great importance.

One of the best evidences of the increasing importance of mining and of the great interest that is being taken in it by the general public is the fact that the mining schools and colleges throughout the country report large increases in the numbers enrolling. In a recent issue the Mining and Scientific Press says that the drift of young men toward mining engineering is illustrated in the number taking the mining course in the University of California at Berkeley which number has increased from 5 in 1892 to 190 in 1900. Probably an even better indication of

FIG. 2.—LATEST TYPE OF GENERAL ELECTRIC 13-TON ELECTRIC MINE LOCOMOTIVE. DRAWBAR PULL, 5,000 LBS. SPEED, 6 MILES PER HOUR.

this increasing interest is the fact that during the same period the number of students in the mining courses of The International Correspondence Schools, of Scranton, Pa., has increased from zero in 1892 when the Schools were first started to about 10,000 at the present time. As these Schools draw their patrons not from any one section, but from all over the United States, Canada, and Mexico and indeed from the whole world, this increase shows that there is a very wide and active interest being taken in mining education.

OBITUARY.

FRANK WILLIAMS.

Mr. Frank Williams, well known by all connected with the iron and steel industries of the country, died at his home, Johnstown, Pa., October 16th, 1900. Mr. Williams was born May 19, 1865, in Johnstown, where his father was superintendent of the Johnstown Water & Gas Co. for many years.

Mr. Williams received his elementary education in Johnstown, and after leaving the high school spent two years in the laboratory of the Cambria Iron Co., entering Lehigh University September, 1883. He there took a course in lurgy, graduating in 1887 with the degree of B. S., and after a year of post-graduate study received the degree of E. M. During his course, he played on the foot ball team and was a member of numerous college societies and organizations both social and scientific. His previous experience in the laboratory of Cambria Iron Co. enabled him to take every advantage of his college training. He was always known as a faithful, practical student and stood among the highest in his class, being a member of the Tau Beta Pi, the honor society for technical students at Lehigh University.

After leaving Lehigh, Mr. Williams accepted a position with the Edgar Thomson Steel Company, and later went to work for the Michigan Steel Company, at Detroit. When he left Detroit he went to Europe to study the basic method of making steel. Upon his return he remodeled the plant of the Horseshoe Company, in Chicago, and later had charge of the East Chicago foundry. While in this position his health began to fail and he was compelled to leave Chicago. After traveling two years, he took charge of the Fayette Manufacturing Company, at Layton, Pa., and several years later was chosen President and General Manager. He organized a brick company in Johnstown, and had charge of the plant here and the one at Layton until a short time ago, when he was compelled to resign his position on account of his health.

Mr. Williams was a member of the Duquesne and University Clubs of Pittsburgh. While a student at Lehigh, he joined the Protestant Episcopal Church of the Nativity. He had been very successful in business, and had accumulated a fortune, \$300,000 of which he left to Lehigh University as a perpetual fund from which loans can be made to students needing money to assist them in obtaining a college education. These loans are to be repaid by the recipients and are to be secured by personal notes of the beneficiaries.

Although Mr. Williams had been in failing health for many years and had been compelled to pass the winters in a milder climate, none of his many friends imagined that the end was so near, and the announcement of his death came as a great shock. He was in every way a manly man, a true friend, and one thoroughly respected by all who knew him or who had ever been associated with him in any way.

JAMES H. BOWDEN.

The many friends of J. H. Bowden, of Wilkes-Barre, Pa., were shocked to hear of his death, which occurred at Meadville, Pa., where he went about the middle of September, suffering with stomach trouble and placed himself under the treatment of Dr. Dewey, the specialist. The treatment progressed favorably, until Thursday, Nov. 15th, when he began to decline rapidly and died on Friday night at 7 o'clock. Mrs. Bowden was with him during his stay in Meadville and was at his bedside at the time of death.

Mr. Bowden was one of the best known mining engineers in the anthracite region and was noted for the originality and cleverness of his designs of mining machinery. He was born at Penzance, in Cornwall, England, in 1846, and came to this country when a small child with his parents. The latter settled in Tamaqua, Pa., where he was reared and received his elementary education. He was apprenticed to the machinist's trade at the shops of Carter & Allen at Tamaqua and completed his trade in Philadelphia, where he afterwards attended a technical school studying to become a mechanical engineer.

He settled in Wilkes-Barre in 1869 and was made superintendent of the Wyoming Valley shops. In 1872 he formed a partnership with Maj. Irving A. Stearns under the firm name of Stearns & Bowden as general engineers. In 1873 he accepted the position of chief engineer of the Susquehanna Coal Co. and later became the chief engineer of all the coal companies connected with the Pennsylvania R. R. Co. He has been borough engineer of Nanticoke from the time of its incorporation until recently. He was one of the first members of the American Institute of Mining Engineers, was a prominent member of the American Society of Mechanical Engineers, and had contributed to the Transactions of these societies at numerous times. One of his latest papers was a

description of the compressed air haulage plant at Glen Lyon which was read at the Canadian meeting of the Mining Engineers in August last. Mr. Bowden held several patents, the most prominent of which is the Bowden self-oiling car wheel, now extensively used in the anthracite region. He was a recognized engineer of great ability and was esteemed highly by the coal companies by whom he was employed. Mr. Bowden recently completed, to be published in the forthcoming history of the Pennsylvania R. R., an exhaustive record of the anthracite coal mining industry of Pennsylvania, as well as a history of all the coal companies now under the management of the Pennsylvania R. R. This work was finished only a short time since, and it is to be regretted he could not have seen its publication. It comprises a record of the anthracite industry from the time of the first shipments to the year 1900, that will prove a most valuable addition to the history of anthracite coal. Deceased was a sportsman of note and was a member of the local asso-

ciation. In private life he was genial and whole-souled and his death is sincerely regretted by a large circle of friends. Mr. Bowden was twice married, his first wife being Miss Juliet Metzgar, sister of Charles B. Metzgar, and the second Miss Eylla Flack. The latter with three children, Helen (Mrs. Fred A. Krell, of Tamaqua), Grace and Dorothy, survive. Mr. Bowden was an attendant at St. Stephen's Church. The funeral was held at his late residence, 49 Park avenue, Wilkes-Barre, on Tuesday, November 20, at 2 o'clock.

The Unwatering of the Comstock Lode.

In response to a letter asking for the present condition of the work of unwatering the Comstock Lode, the Risdon Iron and Locomotive Works, of San Francisco, Cal., which company has charge of this work of unwatering, has replied as follows: "The work of unwatering has been going on for the past year and a half, and we are now down some 420 feet below the Sutro Tunnel. The great difficulty is in getting at the discharge boxes to find out the quantity of water we are discharging. This is almost an impossibility, owing to the position of the discharge adit.

"The Evans elevators are working very satisfactorily indeed, and now that the 2,150 foot level is about unwatered, we propose to establish a permanent base, and to put in a permanent set of pumps at this point. We have been working on this for some time and owing to the lack of pressure water used for operating the Evans Elevators, it will be necessary to put in some other system for the permanent equipment. We intend to use electricity, the electricity being furnished by the Truckee River General Electric Co., the power station

being on the Truckee River near Floriston, at a distance of some 20 to 25 miles from the Comstock Lode. This is now complete and the power will be in Virginia City by the 15th of October.

"The system of pumping proposed to be used is that known as the Joseph Moore system, which is fully described in our catalogue."

Catalogue No. 10 of the Risdon Iron & Locomotive Works contains a description and particulars of the pumps used at the Comstock, and will be found very interesting reading to those who have followed this great undertaking in the unwatering of mines. This company also issues a series of catalogues which describe their dredging and all other kinds of mining machinery.

PROMOTION AND ENCOURAGEMENT OF MINING SCIENCE IN THE UNITED STATES.

DURING the first session of the present Congress an act was passed in the Senate and a bill favorably considered by the Committee on Mines of the House of Representatives, intended to promote and encourage the mining and metallurgical sciences in the United States by appropriating yearly to each State and Territory a certain sum of money for the support and maintenance of a school of mines.

The following are the essential clauses of the bill now before the House of Representatives and which will come before the next session of Congress for action. The sections not here quoted apply merely to details of administration which are not of general interest.

"Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That there shall be, and hereby is, annually appropriated, out of any money in the Treasury not otherwise appropriated, arising from the sales of public lands, to be paid as hereinafter provided to each State and Territory for the establishment and maintenance of schools or departments of mines and mining in connection with the colleges for the benefit of agriculture and the mechanic arts, now established or which may be hereafter established in accordance with the provisions of an Act of Congress approved July 2, 1862, the sum of \$10,000 for the year ending June 30, 1901, and an annual increase of the amount of such appropriation thereafter for five years by an additional sum of \$1,000 over the preceding year, and the annual amount to be paid thereafter to each State and Territory shall be \$15,000."

SEC. 2. "That said appropriations shall be expended only for geological instruction, mining engineering, metallurgy, research in road-building material and its proper application, and the branches of learning pertaining thereto, including the various branches of physical, natural, and economic science and the facilities for such instruction, research, and experiment, in order to promote a liberal and practical education and secure the most intelligent use, conservation, and development of the mineral resources of the country.

SEC. 3. That the benefits of this Act shall apply to the several organized Territories within the United States, and the appropriations hereby made shall be paid, in the manner and on the conditions herein specified, to the colleges for the benefit of agriculture and the mechanic arts now established or hereafter to be established by the legislatures of said Territories, respectively. In any State or Territory where a school of mines has been established by the legislature thereof, separate from the colleges or universities hereinbefore named, the appropriation hereby made shall be paid in the manner hereinafter specified to the duly authorized treasurer of such school of mines.

SEC. 6. "No portion of said moneys shall be applied directly or indirectly, under any pretense whatever, to the purchase, erection, preservation, or repair of any building or buildings: *Provided, however, That a sum not exceeding twenty per centum of any annual appropriation received by any institution may be used in the construction, erection, equipment, or building of special apparatus and machines or plants necessary to carry out the purposes of this Act.*"

SEC. 7. "That a detailed report of all operations conducted by the respective schools or departments of mines, during each year ending the thirtieth day of June, shall be transmitted on or before the first day of the following November to the governor of the State or Territory in which said college or school is established, and a printed copy of said report shall be sent to each school or department of mines herein provided for, and to the Secretary of the Interior. Said report shall contain a statement of all experiments and work of a practical and scientific nature conducted during the preceding year, which may be considered of special value to the mining and metallurgical industries, together with the condition and progress of such school or department, including general information as to the number of its professors and students, its courses and methods of instruction, its library and general equipment. Bulletins or supplementary reports shall be published by said schools or departments from time to time on subjects of importance to the mining community or to the interests of any particular branch of mining industry or mining districts. Such bulletins or reports and the annual reports of the several schools or departments of mines, whether printed separately or as parts of the reports of the institutions with which said schools or departments are severally connected, shall be transmitted in the mails of the United States free of charge for postage under such regulations as the Postmaster-General may from time to time prescribe."

No argument should be required to justify the enactment of such legislation. The mining interests of the country deserve the highest consideration from the Government, which is not here asked to try an educational experiment. By the Acts of 1862, 1887 and 1890, the Government has generously provided for the establishment and maintenance of institutions for the teaching of agriculture and the mechanic arts, and for experiment stations where scientific investigation along agricultural lines can be systematically carried out. These institutions have now been on

trial for nearly 40 years, and the results which they have accomplished are well known, their reputation is world wide, and so much benefit has come to workers in agriculture and in mechanic arts, that there should be no hesitancy or delay in making similar provision for the mining and metallurgical industries.

A number of the Land Grant Institutions have undertaken to maintain mining departments, but the increased demands along the lines for which these institutions were primarily established have, in nearly all cases, necessarily crowded mining instruction into the background, and even where it has been possible to provide instruction in the branches of knowledge relating to mining, it has not been possible to provide the apparatus and equipment necessary for research and experiment.

The era of scientific experimentation and research along mining and metallurgical lines is only just beginning, and the field for development is almost limitless. The laboratory is no longer looked upon simply as a necessary evil about a mine or furnace, but it is rapidly taking its proper place and is now considered an essential and useful adjunct of an up to date plant. This means a higher grade of management and superintendency, and the aspirant for mining honors in the future must recognize that mining and metallurgical engineering are every year being placed upon a higher plane. It is therefore absolutely necessary that there be proper facilities available for those who wish to fit themselves for this higher grade of work.

The enormous increase in our mineral production within comparatively few years has not been due to the discovery of Eldorados, but it has been brought about very largely through the development of methods and processes for treating cheaply large quantities of low grade material, which, only a few years ago, would have been considered worthless and would have been thrown upon the dump. These processes are the direct outcome of laboratory experimentation, and no better example of this can be found than in the rapid development of the cyanide process for the extraction of gold. Without this process South Africa would not now be the world's greatest gold producer, nor would Cripple Creek be the world's greatest gold mining camp.

The amount of the appropriation asked for the first year, \$480,000, is very small compared with the mineral production of the United States for 1899, which was about \$1,000,000,000. An investment of less than one-half of one per cent. of its income would be considered a very meager outlay by any business man along lines that must almost certainly increase the earning power of his business within a very short time. By the appropriation of this money to institutions which are already established, a large amount of the preliminary work will be avoided and the magnificent chemical and mechanical plants which have already been provided at many of the Land Grant Institutions will immediately become available in connection with the proposed courses in mining, so that the beneficial results of such legislation must become apparent in the very near future. As has been noted above, courses of instruction have already been mapped out in many of these institutions, and work along these lines can be pushed as soon as funds are available for properly prosecuting such work.

The funds from which these appropriations are to be taken come from the sale of the public lands, and such use of these funds is in direct line with similar Congressional legislation for educational purposes during the last 40 years.

THE WOLF MEMORIAL FOUNTAIN.

IT IS very gratifying in these days of strikes and controversies between capital and labor, between employer and employed, to report an action having directly the opposite import. The readers of MINES AND MINERALS will recall an obituary notice which appeared several months ago of Mr. John F. Wolf, formerly Superintendent of the Penn Gas Coal Co., Irwin, Pa. A fountain is being erected as a memorial to him in the town of Irwin, which will be known as the "Wolf Memorial Drinking Fountain." This

fountain is 15½ feet high, and is to be surmounted by a life sized statue of Mr. Wolf. The money for the fountain has been raised largely by the miners who were formerly under Mr. Wolf's superintendency, though the business men of Irwin have also contributed. The Council of the city has given the ground needed and will maintain the fountain, while the Irwin Water Company will furnish water to it perpetually. This fountain will be a continued and effectual object lesson illustrating what the relation may be between employer and employe, even at the beginning of the 20th century, pessimists to the contrary notwithstanding.

STANDARD MINE MACHINERY.

THE advantage of standardizing as much of the machinery and as many of the appliances about a mine as possible, is admitted by all, yet when it comes to actual equipment of a plant this principle is often lost sight of almost entirely.

In certain districts each individual mine is a law unto itself and instead of finding uniform or standard appliances at mines operating under very similar conditions, there are as many varieties and types as there are mines. This is by no means a universal rule, and it is encouraging to note that it is a practice that is being steadily changed for the better. The grouping of a large number of mines under one management should and usually does mean the standardizing of every thing possible connected with these mines, thus reducing not only the original cost, but the repair bill as well. Whatever objection may be raised to such combination, this advantage must be admitted by all, as it does not reduce the earnings of the laboring class, and should reduce the price of the marketed product.

One of the best examples of possible improvements and economies in this direction is in the matter of mine cars. In opening up a mine and in laying the track the gauge can usually be selected with respect to the gauge of some standard mine car which is already on the market. It is the height of folly to first lay the track and then have special cars built to suit this gauge, differing possibly from the standard gauge by only a fraction of an inch, and thus greatly increasing the cost of equipment and repairs without in any way increasing the efficiency of the hauling system. Foolish as such a procedure is, how often is it practiced.

When a mine is first being opened up, in the rush to get out some salable product a definite plan of future development is frequently lost sight of, and the old adage that "the more haste the less speed" is being constantly verified in mining practice.

The article by Mr. J. Fox Tallis upon "Welsh Mine Cars," on page 198 of the present issue of MINES AND MINERALS is a plea for some such standardizing in connection with mining operations in the coal mines of Southern Wales. It is doubtful if there is any district in America of equal extent which shows the same amount of variation in the design of its mine cars as is shown by the several different types which we have illustrated, and still more strikingly by the twenty-eight different cars whose dimensions Mr. Tallis has tabulated. An examination of this table suggests a studied departure from anything like a standard, but if we understand correctly the difference between American and British engineering practice, these designs of mine cars are strictly in line with the common British machine design practice.

Although there may not be the same lack of uniformity in our own designs as there is in the illustrations given by Mr. Tallis, we have diversity enough, and there is abundant room for improvement in this line. His suggestions can well be taken to heart and some of his criticisms apply equally to American and British practice. The suggestions in regard to ball bearing wheels and fixed couplings are well worthy of attention, and while the time has probably not yet come for using metal ties in our mines to any extent, there are certain sections of the country where the timber cost is a most formidable item of expense in connection with mining, and anything that will reduce this item of expense is a desideratum.

Mr. Tallis seems to agree with American practice in the material for constructing the bodies of mine cars, as he prefers timber to metal, since the former is much more easily removed in case of a wreck and the cars more easily repaired in case of accident. This objection applies mainly to cars which are run in trips for hauling material over long distances and not to the smaller iron and steel cars which are such great favorites in many metal mines where the cars are mainly pushed by hand for short distances and where they are not run in trips.

A similar comparison of mine cars from American districts would prove most interesting.

TEXAS GEOLOGICAL SURVEY.

DOCTOR WILLIAM B. PHILLIPS has given up his office in Pittsburg to take up work in connection with the Texas State University at Austin, Texas, where he has been appointed to take charge of the field and economic geology work of the University. In this connection he will have charge of the organization and management of a geological survey of the State under the auspices of the University.

The geological work of the State of Texas was very well begun several years ago under Professor Dumble, and it is regretted that the work has been allowed to lapse so long, but the State is fortunate in securing the services of so well equipped and thoroughly scientific a man as Doctor Phillips, who has had a thorough University training, both in America and in Germany, coupled with extensive and varied field experience in geology, mining, and metallurgy. For a number of years Doctor Phillips had a chemical laboratory in Birmingham, Ala., where he was associated with Mr. C. R. Claghorn, at present a well known coal operator of Central Pennsylvania. Since giving up his laboratory, he has devoted himself mainly to expert and experimental work, having carried on elaborate experiments upon the magnetic concentration of the Southern iron ores, while his expert examinations have been made in nearly all sections of the United States, though he has worked mainly in the south, middle, and southwestern sections of the country.

Doctor Phillips has been a frequent contributor to technical literature and is one of the translators of the Wedding's "Basic Bessemer Steel." Judging from the character of his reports which we have seen in the past, and from his other writings, we feel safe in predicting that his geological reports will be of great value to the State of Texas, as they will undoubtedly be reliable and conservative and the boom element will be entirely absent.

The State of Texas is to be congratulated upon its good fortune in securing so competent and well known a geologist and engineer.

BOOK REVIEW.

STATUTORY RULE AND ORDERS FOR THE COAL MINES OF GREAT BRITAIN. Pamphlet 30 pages.

THE LARAMIE CEMENT PLASTER, by E. E. Slosson and R. B. Moudy, Laramie, Wyo. 17 pages.

THE NEW YORK STATE COLLEGE OF FORESTRY ANNOUNCEMENT OF 1900-1901, Ithaca, New York. Cornell University. 35 pages.

THE STATISTICAL YEAR-BOOK OF CANADA FOR 1899, issued by the Department of Agriculture, Ottawa. Price 50 cents. 625 pages.

TRANSACTIONS OF THE NEW SOUTH WALES CHAMBER OF MINES, September 1900, R. J. Etheridge, Secretary, Sydney, New South Wales.

OHIO STATE UNIVERSITY. Thirtieth Annual Report for the year ending June 30, 1900. This is a detailed statement of the faculty, students and courses of the University.

POCKET COMPANION CONTAINING USEFUL INFORMATION AND TABLES APPERTAINING TO THE USE OF STEEL, as Manufactured by the Carnegie Steel Company, Pittsburg, Pa. Price \$2.00. 319 pages. This edition of 1900 does not differ materially from that of 1896, the same general arrangement and style being followed.

UNITED STATES GEOLOGICAL SURVEY BULLETINS, Washington, D. C. "The Production of Antimony in 1899," 8 pages; "The Production of Fluorspar in 1899," 4 pages; "The Production of Mica in 1899," 6 pages; "The Production of Phosphate Rock in 1899," 26 pages, by E. W. Parker. "The Production of Iron Ores in 1899," 41 pages, by John Birkinbine.

ANALYSES OF PIG IRON, Collected and Published by Seymour R. Church, San Francisco, Cal. Price \$2.50, post-paid to any part of the United States or Canada. 173 pages. A collection of iron ore analyses with a few photographs of blast furnaces and a number of full sized illustrations showing very nicely the grain and appearance of certain typical brands of pig iron.

BULLETIN DE LA SOCIÉTÉ DE L'INDUSTRIE MINÉRALE. Volume 14, 3 parts, 3 series. 479 pages, published by J. Thomas & Co., Saint-Etienne. First Part. A report prepared for the International Congress of Mining and Metallurgy held in connection with the Paris Exposition. This report is divided into two sections. 1st, the Employment of Explosives in Mines. 2nd, Condition of Exploitation at Great Depths.

ANNUAL REPORT OF THE SMITHSONIAN INSTITUTION, UNITED STATES NATIONAL MUSEUM, WASHINGTON, D. C., Chas. D. Walcott, Acting Assistant Secretary, in charge of the United States National Museum. 1,270 pages. Part I contains the report of the organization of the National Museum. Part II, which includes all but 153 pages, has a scientific discussion of the Crocodilians, Lizards, and Snakes of North America, by Edward Drinker Cope.

FAMOUS GOLD NUGGETS OF THE WORLD, by Thomas Jefferson Hurley, No. 33 Wall Street, New York City. 64 pages.

This pamphlet contains some interesting facts about some of the world's nuggets, but its name is far too comprehensive, as it treats of only a few of those that have been found in America. Typographically it is poorly gotten up and the arrangement of the book is not of the best.

PROGRAM OF EXCURSIONS OF THE AMERICAN INSTITUTE OF MINING ENGINEERS UNDER THE AUSPICES OF THE CANADIAN MINING INSTITUTE AND MINING SOCIETY OF NOVA SCOTIA. This very interesting souvenir was presented to the American mining engineers who visited Canada during the last summer. It contains a large number of very interesting photographs of Canadian mining matters and a description of the plants illustrated in the photographs.

AMERICAN INSTITUTE OF MINING ENGINEERS, 99 John St., New York City, the following papers have been received: Lindgren, Metasomatic Processes in Fissure Veins; Carpenter, Pyritic Smelting in the Black Hills; Herzig, A Method for Obtaining the Volume of Small Drifts and Working-Places, Where it is Impossible to Use a Transit; Rickard, The Telluride-Ores of Cripple Creek and Kalgoorlie; Wilkinson, A Mining Survey; Page, The Explosion at the Red-Ash Colliery, Fayette County, West Virginia; Hamilton & Withrow, The Progress of Mineralogy in 1899.—Bulletin No. II: Discussion, Coal Outcrops; Discussion, A New Method for Working Deep Coal-Beds; Postscript, The Oil-Bearing Shales of the Coast of Brazil. List of Members

ILLUSTRATED CATALOGUE OF NARROW GAUGE LOCOMOTIVES. Adapted Especially to Gauges of 3 feet 6 inches. 452 pages. Baldwin Locomotive Works, Philadelphia, Pa. Although nominally a catalogue, this volume is much more than the ordinary name catalogue implies. The first 89 pages are devoted to a history of the Baldwin Locomotive Works, which means a history of the locomotive construction in the United States, and which contains a large amount of very interesting historical matter. This is followed by a number of pages of data upon the hauling capacity of the locomotive, general specifications, and physical tests of the materials of construction. Then come detailed descriptions of a large number of narrow gauge locomotives, all very thoroughly indexed. The work is a most excellent example of typography, and is another of the textbook book catalogues which have now become a necessary part of every scientific library.

DEPARTMENT OF MINES AND AGRICULTURE, Sydney, New South Wales. Annual Report of the Department of Mines and Agriculture of New South Wales for the year 1898, 203 pages, contains the following papers: Diamonds: Their Occurrence in New South Wales, by D. C. McLachlan, for 1899, 18 pages. Report on the Hillgrove Gold-Field, by E. C. Andrews, B. A. Mercury, or "Quicksilver," in New South Wales, with Notes on its Occurrence in other Colonies and Countries, by J. E. Carne, F. G. S., 36 pages. The Copper-Mining Industry and the Distribution of Copper Ores in New South Wales, by J. E. Carne, F. G. S., 197 pages. Report on the Wyalong Gold-Fields, by J. A. Watt, M. A., B. Sc., 40 pages. Notes on the Occurrence of Bismuth Ores in New South Wales, by J. A. Watt, M. A., B. Sc., 11 pages. Notes on Gold Dredging with Reference to the Introduction of the Industry into New South Wales, by J. B. Jaquet, A. R. S. M., F. G. S., 21 pages. Notes on the Occurrence of Tungsten Ores in New South Wales, with a Register of Localities, by J. E. Carne, F. G. S., 9 pages.

MANUAL OF EXPLOSIVES. A Brief Guide for the Use of Miners and Quarrymen, by Courtney DeKalb, Professor of Mining, Kingston School of Mines. Issued by the Ontario Bureau of Mines, Ontario. 126 pages. This is an excellent little book which has been prepared by Professor DeKalb for the Ontario Bureau of Mines for the benefit of the Mine Managers, Foremen and all others in the Province having charge of explosive materials. The author says in his letter of transmittal that it is partly a compilation from the literature upon explosives, partly the result of direct inquiries from recognized authorities, and is also based upon his own experience in the use and testing of explosives. He does not claim it to be an exhaustive treatment of the subject in any way and frequently refers the reader to the more complete works on the subject. It will undoubtedly prove a most valuable assistant to the mining men of Ontario, and great credit is due the Ontario Bureau of Mines in issuing so useful a manual.

THE METALLURGY OF GOLD, by M. Eissler, Fifth Edition, Enlarged and Rearranged. Crosby Lockwood and D. Van Nostrand Company, New York City. 625 pages. Price \$7.50. That a fifth addition of this work within twelve years after its first appearance should be required is a most favorable commentary upon the favor with which the previous editions have been received. The book is too well known to need description, excepting the changes that have been made in the present edition, where a large number of new diagrams, halftones and other very excellent illustrations have been introduced. The book has been enlarged and its appearance generally improved. A complete rearrangement of the text has been made with advantage and this is a decided improvement, as some of the earlier issues were open to criticism of poor arrangement.

Part I is introductory and treats of the general properties of gold and of hydraulic mining and metallurgy. Part II, the Mining of Gold. Part III, Treatment of Gold Bearing Ores. Part IV, Hydraulic Metallurgy of Gold Ore. Part V, The Cyanide Process. Part VI, Testing and Refining of Gold.

PROGRESS OF INVENTION IN THE NINETEENTH CENTURY, by Edward W. Byrn, A. M., Published by Munn & Co., 361 Broadway, New York City. 476 pages profusely illustrated. Price \$3.00. The author in his preface acknowledges that he is undertaking an ambitious task and disclaims any effort to a complete review of the progress of invention during the nineteenth century, recognizing that such an effort would fill many volumes the size of the very interesting one he has prepared. It would be very easy to criticize the author of such a work for omissions, but it is only fair to judge by what he has done and not by what might have been done, as the field covered by the subject is practically limitless. In the first chapter an interesting perspective view is taken of inventions during the nineteenth century, and in Chapter II, the author gives a very interesting chronology of its leading inventions. Then follow 33 chapters under the following heads: Electric Telegraph; Atlantic Cable; Dynamo and its Applications; Electric Motor; Electric Light; Telephone; Electricity, miscellaneous; Steam Engine; Steam Railway; Steam Navigation; Printing; Typewriter; Sewing Machine; Reaper; Vulcanized Rubber; Chemistry; Food and Drink; Medicine, Surgery and Sanitation; Bicycle and Automobile; Phonograph; Optics; Photography; Roentgen or X-Rays; Gas Lighting. Civil Engineering; Wood Working; Metal Working; Fire Arms and Explosives; Textiles; Ice Machines, Liquid Air. From this list it will be seen that the author has made an interesting selection. The text is most interestingly illustrated and the book both intensely interesting and valuable.

MINERAL LAW DIGEST, by Horace F. Clark, Charles C. Heltman and Charles F. Consaul. Price \$7.50. 538 pages. Callaghan & Co., Chicago, Ill. This Digest contains a section of the United States revised statutes. Under the section given there are arranged the regulations of the Land Office pertaining to the subject matter of that particular section of the statute, and following the regulation is a digest of decisions upon points arising under that particular section of the statute. Part II of the book contains a Manual of Procedure intended as a guide to all mining claimants in the various steps necessary to secure a patent for his claim. Part III contains samples of the various "forms" used in connection with the location of mineral claims. The text is well printed and well arranged, and the book is a very handy reference book for any one wishing to attain a general idea of the subject of mining claim locations.

THE MINERS MANUAL. United States, Alaska, The Klondike. Callaghan & Co., Chicago, Ill. Price \$2.50. 404 pages. This work is to a certain extent a condensed form of the preceding. It is divided into four parts as follows: Part I. A brief treatise upon the land acquired by location entry with a description of the various steps for the acquisition of the title. Part II. The "Mineral Land Statutes" of the United States with the latest regulations for the Department of the Interior. Part III gives "forms" for use in acquiring and transferring title to mining claims, and includes a chart of mining terms. Part IV gives a general description of Alaska and Klondike.

PERSONALS.

Mr. Guy C. Orme has recently left Mexico and his present address is Owenmore, Croosmolina, County Mayo, Ireland.

Mr. Hugh MacDonald, of Pittston, Pa., for some years past Mine Inspector of the 3rd anthracite district, has been reappointed by Governor Stone for another term.

Mr. Frank Webster, link-belt engineer, has opened an office at 1501-2 Park building, Pittsburg, where he will represent the Link-Belt Engineering Co., of Nicetown, Philadelphia, Pa.

C. W. Pritchett, Jr., who has recently been in assay work in Mexico, has returned to the United States and his present address is Box 393, Denver, Colorado, where he is engaged in mining engineering work.

Mr. Frank P. Kendrick, well known in the lower anthracite mining regions, is now located at Lead Hill, Mo., as Superintendent of the Midland Zinc and Lead Co., with mines and works at Lead Hill, Wright County, Mo.

Professor M. C. Ihlse, for the past seven years Professor of Mining and Geology at the Pennsylvania State College, has resigned from that position to take up new work in connection with the Brooklyn Polytechnic Institute of Brooklyn, New York.

Mr. Spencer Miller, Chief Engineer of the Cableway Department of the Lidgerwood Mfg. Co., New York City, has returned from Europe after a four months' absence. It is understood that his latest invention, the marine cableway for coaling at sea, will be taken up by several of the navies of Europe.

Mr. Edward H. Coxe, for some time past engineer of the Boomer Coal & Coke Company, of Boomer, W. Va., has resigned his position to take effect November 30, and has accepted a similar position with the Jones & Adams Company, of Chicago, Ill., operating mines at Caltin and Springfield. Mr. Coxe will reside at Springfield.

Captain R. G. Dill, who is thoroughly conversant with the mining interests of the West has been made mining editor of the *Denver Times*. Captain Dill has had long experience both in the mining field and in newspaper work, and the *Times* promises, under his direction, a daily department of mining intelligence superior to anything yet attempted in the State.

One of the latest reported trusts or consolidations in the mining and metallurgical line, is a company known as the Allied Cyanide Companies of America. This is a combination of the Gold and Silver Extraction Company of America, Limited, and the Cassel Gold Extracting Company, Limited, of Glasgow, Scotland. The capital is said to be £110,000, divided into 110,000 shares at £1 each; 35,000 of these shares to be preferred. The directors are Wm. Forrest of the McArthur-Forrest process, J. R. DeLamar the well known mining man of the West and Northwest, and Henry A. Jones, Managing Director of the Cassel Gold Extracting Company. The company is to be under British management with an advisory board in Denver, Colo., consisting of the Messrs. Hugh Butler, W. H. James, Philip Argall, and Geo. A. Anderson, the latter to be general manager. It is also rumored that the combination may include the manufacturers of the cyanide, so as to embrace all branches of the business of extracting gold by the cyanide process.

Alexander Car Replacer.

A derailed car is hard enough to handle above ground but underground the difficulties are multiplied many times owing to lack of side room, low roof, poor light and the many other disadvantages incident to underground haulage.

The Alexander engine and car replacer, here illustrated shows a very neat and efficient device for quickly placing a derailed car back on the track again. These replacers are in use on a large number of the railroads in the United States and foreign countries and the testimonials of a large number of users testify to their efficiency. The replacers are made in three sizes, the two smaller sizes being particularly applicable for mine use. The No. 2 replacers weigh 140 lb. per pair, apply to rails $4\frac{1}{2}$ to $5\frac{1}{2}$ inches high and sell for \$16 per pair. The No. 3 weigh 50 lb. per pair, apply to a rail $4\frac{1}{2}$ inches high and sell for \$12 per pair. A trial pair of these "replacers" will be sent by the Alexander Car Replacer Manufacturing Co., of Scranton, Pa., freight prepaid to any point east of the Missouri River.

CORRESPONDENCE.

This Department is intended for the use of those who wish to express their views, or ask or answer questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided. All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith. The editor is not responsible for views expressed by correspondents in this Department. Correspondence should be in as simple language, and as free from technical terms and formulas as possible, consistent with clear solution. Questions on subjects not directly connected with mining will not be published.

Title to Mining Claim.

Editor Mines and Minerals:

SIR:—I have a mining claim on Sec. 32 School Land in the State of Utah which the State is about to sell. I am not prepared with means or work done to apply for a Patent, or to contest with the State unless I have to. If I buy the land of the State will it give me a good title to my mining claim or would I still have to defend myself against prospectors by getting mining title from the United States.

Yours truly,
J. H.

Carbon County, Montana.

Editor Mines and Minerals:

SIR:—This is the Carbon county of Montana, and contains large deposits of high grade lignite coal as at Red Lodge, bituminous as at Bridger and semi-anthracite as at Carbonado. They are at present drilling for oil in the southwestern part of the county, with every prospect of success. The mineral deposits in this section border on the southwestern part of this county and from thence down into Wyoming. The shaft here is 900 ft. from top bunton to top of coal, vein 5 ft. thick; tippie built for the Anaconda Copper Mining Co., by Gillett-Herzog Co., of Minneapolis is suitable for double deck cages and is 115 ft. from ground to sheave wheels. All construction is of steel and brick. The mine was only recently opened, and the farthest distance from shaft is 1,300 ft. There have been some recent valuable discoveries of copper deposits in the Sun Light district, southwest of here. An analysis of Carbon coal is as follows: Fixed carbon, 46.76; volatile matter, 40.51; ash, 10.73; sulphur, .20; moisture, 1.80.

Carbonado, Mont.

Yours truly,
E. C. S.

Machine Mining in Illinois.

Editor Mines and Minerals:

SIR:—Kindly inform me of the present condition of machine mining in Illinois and Iowa and under what conditions it is carried on.

Birmingham, Ala.

Yours truly,
THOMAS JONES.

Mr. Herman Justi, Commissioner of the Illinois Coal Operators' Association, has kindly answered this question as follows:

"Our current State agreement with the miners' union fixes the machine differential at 10 cts. in the Danville district and 7 cts. throughout the balance of the State. I believe a good many if not all the mines in the Danville district have discontinued the use of their machines on account of the hostility displayed by the individual miners, and not on account of any action taken by the union. The use of machines has been discontinued at other points in the State, though at how many mines I could not say, because of the smallness of the differential, some operators claiming that 7 cts. was not sufficient to cover repairs; in fact it only amounts to 6.4 cts. because there is no charge for pick sharpening in the machine mines, whereas in the hand mines there is a charge of $\frac{1}{2}$ cent for blacksmithing. However, there are new machine mines being opened in several districts.

"We are not specially posted in regard to Iowa, though it is my understanding that machines have never been used extensively, if at all, in that State on account of the thinness of the seams and the limited areas of workable coal."

When we visited the mines of the Danville district in June, 1900, there were no machines running but we are informed that since that time several of the mines have resumed their use.

British Columbia Boundary District.

Editor Mines and Minerals:

SIR:—The mining outlook in the Boundary district of British Columbia is steadily improving now that several of the mines have entered upon the shipping stage. The aggregate tonnage of ore sent out during four or five months ending September 30 exceeds 25,000 tons. About half of this quantity was shipped

during the month of September. Both mining and transportation facilities have been and are still being improved, and provision for treatment of the ore is also being made on a larger scale. The Trail smelter is now in shape to treat more ore than at any previous time, whilst the Granby smelter, at Grand Forks, B. C., which started on August 21st last with one 300-ton stack, now has a second furnace of similar capacity ready to be blown in. The buildings, ore bins, railway trestles and tracks, etc., for the British Columbia Copper Company's smelter at Greenwood are about completed and the machinery for the plant is arriving and is being installed. This smelter will probably be ready for operation before the close of the current year. The Standard Pyritic Smelting Company will begin the erection of its smelter near Greenwood on October 1st and expects to have it completed in December next. These several smelters should be fully equal to all ordinary requirements of the district until more mines shall have been opened up and the output of ore considerably increased.

The principal copper-gold mines of the district are the Knob Hill and Old Ironsides group (owned and jointly operated by what are known in Canada as the Miner-Graves companies); the Mother Lode, owned by the British Columbia Copper Company, of New York; and the B. C., which is the property of the B. C. Chartered Company, of Montreal, Quebec. There are numerous other properties, some of which have shipped a comparatively small quantity of ore, that are promising, but speaking generally their financial backing is not yet strong enough to ensure their being developed on a scale sufficiently large to demonstrate within a reasonable time whether or not they will make permanent mines. Of course there are several exceptions, as will next year be demonstrated by three or four being added to the list of regular shippers. Besides these copper properties there are some with ore carrying values chiefly in gold. Prominent among these is the Jewel, in Long Lake camp, in which a fine gold-quartz ledge has been opened up to a depth of 350 feet. The English company owning this mine intends putting in a stamp mill and probably a cyanide plant, but the latter will be determined by the results obtained from ore now being sent to chemical works near Rossland for treatment.

The Old Ironsides and Knob Hill are together giving employment to 170 men. A new 10-drill air compressor has lately been added to the plant on these mines and after this shall have been put in operation the working force will be increased to the full capacity of the mines to employ miners to advantage. It is anticipated that there will soon be between 200 and 250 on the payroll. The No. 2 shaft on the Old Ironsides is down 400 feet, and altogether there have been done in underground development of this group about 9,000 feet of work. Ore shipments to date exceed 14,000 tons.

Some 65 men are at work on the Mother Lode. Its main shaft is 325 feet in depth and much development work has been done on the 200 and 300-foot levels, especially on the former. A big shoot of ore has been shown by drifts and cross-cuts to be from 80 to 100 feet in width and 400 feet in length, passing thence underfoot from the 200. It has been entered on the 300 ft. but not explored for any great distance along its length at this lower level. A commencement has been made to sink the shaft to the 500 ft. level, which will be reached early in the new year. Altogether development work done in this mine approximates more than 5,000 feet.

The B. C. mine was the first in the district to ship regularly to the smelter. Its total output to date is about 10,000 tons. Its present depth is only 272 feet, with ore stopes on three levels, the deepest being 260 feet. Preparations are now being made to sink deeper and in other ways to more extensively develop this mine, for which its present owners are understood to have two years ago paid \$300,000.

The larger mines in this promising district are in the charge of mining engineers who have had practical experience in some of the most important mining camps in the United States, so they are in fully capable hands. A large amount of capital has already been spent in building railways, erecting smelters and equipping and developing mines, but the outlook is very favorable for an ample return resulting.

Greenwood, B. C.

Yours truly,
E. JACOBS.

Outside or Inside Packed Pumps.

Editor Mines and Minerals:

SIR:—Thanking you for the excellent exposition of the principles and action of pumps in the article on "Draining and Pumping in Mines," in your September issue of MINES AND MINERALS, I again with many others, would enjoy a few words from you, or if you prefer, to have it discussed in your correspondence column, on the following questions:

Is there any difference in the action of the atmospheric pressure on a common plunger pump with one end of the plunger exposed to the atmosphere, and on a central, outside or inside

packed plunger which has neither end exposed to the air? Both kind of pumps being double acting.

Is there any difference in the pressure or resistance from the bottom valve to discharge point; and consequently, greater strength of material required in one pump than in the other? If a mathematical illustration is to be given, let us have it on a pump of the following dimensions: Diameter of pump 10 inches, stroke 3 feet, lift of pump from sump to discharge point 100 feet, with pump set 23 feet above the water in the sump. We place the pump at this point because a mine pump with less than 15 or 20 feet from the general level of the water in the sump to the bottom of the top valves has too little sump storage room or reserve to give practical satisfaction.

As these central packed pumps are getting into much more general use, it would be of interest to mining men to know their advantages and disadvantages. Very truly yours,
Pittston, Pa. D. W. EVANS.

There is no difference in the action of the atmospheric pressure in the two styles of pumps given. In both cases the pressure of the atmosphere is exerted alike upon the water column at its point of discharge, and upon the surface of the water in the sump or basin. This atmospheric pressure becomes a positive pressure exerted against each side of the piston or plunger. This is the case whether one end of the plunger is exposed to the atmosphere or not. The only difference that occurs in reference to the pressure under which the piston or plunger of a pump moves, is in the case of single acting or double acting pumps. In both of these types the atmospheric pressure is exerted alike upon both ends of the plunger, either acting directly upon the plunger itself or through the water column. Thus, if one end of the plunger is exposed to the atmosphere, the atmospheric pressure acts upon that end of the plunger directly; but where the end of the plunger is not exposed to the atmosphere, the atmospheric pressure acts through the water column. In double acting pumps one end of the plunger may be exposed directly to the atmosphere, as in the case in those pumps using two plungers connected by outside yokes and rods, both plungers moving in the same direction. This is the common form of the Jeaneville pumps and other types, and these are outside packed. When the plunger is inside packed, neither of its ends is exposed directly to the atmospheric pressure. In single acting pumps on the other hand, one end of the plunger is always exposed directly to the atmospheric pressure. In neither of these cases, however, is the pump required to lift the atmospheric pressure in addition to the water column. The only difference between the two types of action, double acting and single acting pumps, is that in the single acting pump the pump is required to lift but one water column at a time. For example, in the forward stroke of a single acting pump the pump lifts the water column at its discharge end, while in the backward stroke it lifts the water column at its suction end. The weight of either one of these two columns is held alternately by its respective valves while the pump is lifting the other column. In this case only, is there any decrease or increase of the load upon the plunger of the pump due to its style of action. The atmospheric pressure in no case acts to increase the load upon the pump or to decrease it; as far as the water cylinder is concerned.

The action of the total or absolute pressures exerted upon the two ends of the piston or plunger of a pump, in both the single acting and the double acting pumps, will be more clearly understood by tabulating these pressures as below. All of these pressures are exerted against the plunger or piston, except only the pressure of the water column at the suction end of the plunger, which is exerted in a direction away from the plunger. We may thus speak of these pressures as being positive or negative according as they are exerted toward the plunger or away from it. We have indicated these two kinds of pressures by the positive (+) and negative (—) signs.

SINGLE ACTING PUMPS.			
	Discharge End.		Suction End.
Forward stroke	+ Atmospheric pressure + Water column		+ Atmospheric pressure
Backward stroke	+ Atmospheric pressure		+ Atmospheric pressure — Water column
DOUBLE ACTING PUMPS.			
	Discharge End.		Suction End.
	+ Atmospheric pressure + Water Column		+ Atmospheric pressure — Water column

In every case the effective pressure upon the plunger or piston of a pump, or the effective head under which the pump operates, is the difference between the absolute or total pressures upon the two ends of the plunger or piston. We observe that if we subtract the total pressure upon the suction end from the total pressure upon the discharge end, in either of these types, we obtain the pressure head against which the pump is operating. Doing this we find that in single acting pumps the pressure head

in the forward stroke is the water column above the pump, or the discharge column, while in the backward stroke the pressure head is the water column below the pump, or the suction column. In double acting pumps we find the effective head to be the sum of the two water columns or the total water column from the sump level to the point of discharge at the surface. The atmospheric pressure upon the two ends will be observed to balance in any case.

The statement that central packed pumps are coming into more general use may be questioned. This class of pumps for mine work has few if any advantages, while its disadvantages are numerous. It is true for light pressures inside packing does fairly good work. The only positive advantage in its favor that we recall at present is the fact that sometimes one central plunger packing takes the place of two outside plunger packings, but even then a small packing is required around the plunger stem. When inside packing is used the condition of the packing is not readily observed; water may leak past the plunger from one side of the piston to the other without being observed. This will greatly reduce the efficiency of the pump, and the cause may be unknown for a long time. Outside packing is readily renewed at any time with little trouble and delay, while the renewal of inside packing requires the drainage of the pump and the removal of the cylinder head.

Correction.

The article upon the "Compressed Air Locomotive," by Mr. H. K. Myers, which appeared in the November issue of MINES AND MINERALS, has been very favorably received and commented on. The following typographical errors should, however, be noted in the article: The formula for tractive effort (p. 188) should read $\frac{d^2 \times l \times x p}{D}$, not $\frac{d \times l \times x p}{D}$. The formula on page 189 should be $V = V' \frac{p}{p'}$, not $V = V' \frac{p}{p' + p}$. $V = 975 \frac{130}{650 - 130} = 244$, not $V = 975 \frac{130}{650 + 130} = 244$. Omit inch marks ("in" or ") wherever used in the article in giving amount of cut-off. Page 189, 1st line, should be .98 not .95.

Attention has also been called to the fact that some of the arithmetical work is not exact. Mr. Myers intimated this by his statement that his calculations were made with the slide rule, and although the results published are accurate enough for all practical purposes; still lest such values may be misleading to some, the following slight changes in arithmetical values may be noted:

Page 189, first column, 6th paragraph, should read [5,400 × 6 = 32,400, but 32,000 would almost invariably be assumed.] We will, therefore, assume the necessary weight of the locomotive to give the proper adhesion as 32,000 lb., and we calculate that the tractive effort necessary to haul itself up the 3.5 per cent. grade would be 3.5 ÷ .5 = 4 per cent. (.5 per cent. covering the friction of the locomotive on the level) of 32,000 lb., or 1,280 lb., to which we add the necessary drawbar pull to haul the desired load, 1,280 + 5,400, and have a total tractive effort of 6,680, which is about the limit of our locomotive on dry rail with sand.

By consulting the table No. 1 we see that, at 100 lb. working pressure, a 10 in. × 14 in. 26 in. driver locomotive has a maximum tractive effort at $\frac{1}{4}$ cut-off, which is practically full stroke, of 5,280 lb., and by dividing this into our necessary tractive effort, we find that the necessary working pressure would be about 130 lb. [$\frac{5280}{40} = 132$ but 130 would ordinarily be assumed.]

Page 189, 2nd column. The length of haulage should be 5,370. In answer to an inquiry as to how Table No. 1 was calculated, Mr. Myers says:

"In making calculations of Table No. 1 I used formula $T. E. = \frac{d^2 \times x p \times l}{D}$ in which x is as follows: For $\frac{1}{4}$ cut-off, .98; $\frac{1}{2}$, .95; $\frac{3}{4}$, .88; $\frac{1}{4}$, .80; $\frac{1}{2}$, .68; $\frac{3}{4}$, .51; and $\frac{1}{4}$, .31 and $p = 100$. The relative values of x are .98, $\frac{1}{2}$, .96, $\frac{1}{2}$, .90, $\frac{1}{2}$, .83, $\frac{1}{2}$, .72, $\frac{1}{2}$, .58, $\frac{1}{2}$, and .40, $\frac{1}{2}$ for expansion of air and in order to give a safe value to x I worked from absolute pressures.

"Thus, with a gauge pressure of 100 the absolute is 115 lb. and for $\frac{1}{4}$ cut-off whose corresponding factor is .40 we have .40 × 115 = 46 lb. less 15 lb. at atmospheric pressure gives 31 as the M. E. P. for $\frac{1}{4}$ cut-off. In the late cut-offs this is a matter of little importance, but as a matter of safety should be considered."

South Pass, Wyoming.

Editor Mines and Minerals:

SIR:—The past summer has been one of considerable activity in the mining fields of the West, and the South Pass country has had its portion considering the fact that it is isolated from any railroad. Since my former letter the Carrisa Mine—now incorporated under the name of the Federal Gold Mining Company—

has opened up three large ore shoots carrying high values in gold. The property is now opened up to a depth of three hundred feet, with levels driven each way on the vein. The mill is run one shift owing to a scarcity of water; a thing that has never occurred in this section before. Mr. Charles Van Sickle, one of the principal owners of the mine, is here at present writing. He is making arrangements for the spring work, which will be carried on under the management of B. U. Tibbals. East of the Carrisa mine and joining it is the Dewey property operated by the New England Company, the same company owns or controls the Smuggler-Union property in Colorado. Mr. Geo. Leighton, the manager, has a small force at work, developing the property, but as it is in litigation no one not interested can learn anything as to the extent and richness of the ore bodies that are opened up. Two miles east and in the same belt is the Mary Ellen mine, incorporated and worked under the control of the South Pass M. & M. Co. This property is owned principally by Colorado men. The mine lies in a granitic porphyry zone—that has intruded up through the gneissic schists; it has a varying width of from a very few inches to two and one-half feet, and is composed of a white quartz containing free gold in paying quantities as well as iron sulphide rich in values. Mr. J. P. Ibsen, of Denver, Colo., the manager, has sunk the shaft down to a depth of two hundred feet; and is now drifting both ways on the vein with a view of opening up four rich shoots that are known to exist. Since taking charge of the property this spring he has erected on the ground a Huntington mill and hoisting plant. Both plants are under one roof.

On the same mineral belt and about one-half mile east of the Mary Ellen property is the St. Louis. This mine is worked under lease and bond by Messrs. Carr, Hoisington & Co. They extracted several tons of high grade ore this season which they have just finished running through the Sherlock-Marrin mill above South Pass. The lessees have opened up a large body of low grade ore which can be successfully treated by the Waugh-Bignell dry concentrating process, but as Messrs. D. E. Thompson, Bignell and Waugh have not erected a custom plant the lessees will not take out the ore until spring.

The Garfield mine is on a different mineral belt from the former mentioned mines, but the belt intersects the Carrisa mineral zone at or near the east end line of the Carrisa mine and from there it has a more northerly trend than the first mentioned belt. This property has been worked more or less for the past thirty years and has been very productive in gold. Mr. D. E. Thompson and E. Bignell, superintendent of the B. & M., are interested in the property and have a bond and lease on it. They have erected a Chilean mill and have a Waugh-Bignell dry concentrator of twenty tons capacity at work. The mine and mill are equipped with a complete electric plant of eighty H. P. From a test of the Garfield ore which assayed \$8 per ton they succeeded in raising the value of the concentrates up to \$1,059.55 per ton, leaving 83 cents value in each ton of tailings run through the concentrator. As there are large bodies of low grade ore in this and other properties, the Waugh-Bignell process will do much toward bringing in capital from the outside. The geological features of this mine have been well spoken of by Professors Hayden, Comstock, and others.

The Rose mine is situated about one-half mile west of the Garfield (Buckeye) mine and is therefore one and one-half miles west of Atlantic City. This property is being worked by Mr. R. M. Ricketts, who has opened up the vein in such a manner as to show a large body of high grade gold ore that averages over one hundred dollars per ton. Some of the ore is said to carry tellurium in good values. Like all other mines in this field, the vein is lying in the metamorphic rocks.

The Granier placer mines that have been laying idle for a number of years have changed hands. Mr. D. G. Cahoon, of Potsdam, N. Y., having succeeded in inducing a rich syndicate to work the property, and under the superintendency of Messrs. Giessler and Ibsen the many miles of ditches and flumes have been put in repair and all arrangements to work the placers next spring have been made. The gravel covers an extensive area and is very rich. Besides the miles of valley along the Rock Creek, there are thousands of acres of a glacier deposit which carries values.

The Granier placers were first operated fifteen years ago, by a company of Frenchmen, under the management of Mr. Emile Granier, of Paris, France. The company spent large sums of money constructing ditches, flumes, and dams, but from some cause the ground was never made to pay though it was rich in gold; some of the ground running as high as thirty dollars to the cubic yard. Though Mr. Granier tried hard to get experienced placer miners, he failed as subsequent facts, which have come to light, prove. The new company can make the property pay if the same is handled intelligently and in a business like manner. The entire South Pass mining region is situated on a high

plateau near the summit of the Rocky Mountains and is composed of an igneous and metamorphic formation, as late tests have demonstrated, for numbers of samples sent to the School of Mines, of Colorado, and other leading institutions of the country, have been tested and pronounced to be dolomite, gneiss, diorite, phonolite, granite, and syenite. What developments will prove this section to be, remains to be seen. A move is being made to have Mr. Arthur Lakes, of Denver, Colo., come in here next spring and examine and report on the country.

South Pass, Wyo.

Yours truly,
ED. HARRIS

CATALOGUES RECEIVED.

In writing for catalogues, please mention Mines and Minerals.

- M. C. BULLOCK MFG. Co., Chicago, Ill. "Hoisting Machinery," 32 pages.

Direct-Current Engine Type Generator, 250 volts, particularly constructed for supplying power to motors operating machine tools, cranes, elevators, ventilators, pumps, rolls, drills, cutting machines, etc., in factories, mills and mines. These generators also permit of the operation of both arc and incandescent lamps from the motor circuit.

PRIZE CONTEST.

Prizes Given for the Best Answers to Questions Relating to Mining.

For the best answer to each of the following questions, the value of \$1 in any of the books in our book catalogue, or six months' subscription to MINES AND MINERALS.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue, or three months' subscription to MINES AND MINERALS.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to MINES AND MINERALS.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition Contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed to us not later than one month after publication of the question.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Ninth—In awarding prizes, other things being equal, a carefully written and arranged answer will be given the preference.

Competition Questions for December.

QUES. 619.—Siphoning From a Shaft.—We have a shaft 50 feet in depth sunk on a hill. The shaft is making 4,000 gallons of water per hour. At a short distance from the mouth of the shaft is a steep ravine that descends to a river 100 feet below the depth of the shaft. It has been suggested that a siphon could be used advantageously to handle this water. If this accords with what you would advise please say so, but if not, state how you would proceed to handle this water if you were placed in charge of the mine.

QUES. 620.—Will Ventilation Cease if Fan Is Stopped?—We have a mine ventilated by means of two shafts, a downcast shaft having a depth of 300 feet, and an upcast shaft whose depth is 500 feet. The ventilator is a blow-down fan, which furnishes a current of 40,000 cubic feet of air per minute in the mine. The development of the mine has been such that the length of its airways from the foot of the downcast to the foot of the upcast shaft is practically 50,000 feet; the double-entry system being used. If the fan is suddenly stopped for repairs will the air current continue to circulate through the mine, or will all circulation in the mine cease?

QUES. 621.—Gob Fires In Abandoned Workings.—The mine of which I have charge is troubled with gob fires in the abandoned workings near the shaft bottom. The fire walls and brick stoppings which we have used to close off these abandoned workings are only partially effective. Owing to shaly roof and porous character of the coal, sufficient air is still supplied to the workings to render the fire a constant menace to the mine. The mine is worked on the room and pillar system, with double entries, and is ventilated by means of an exhaust fan. Will you kindly suggest what in your opinion would be the most effectual manner of treating this fire both with respect to the present and future good working of the mine?

QUES. 622.—Blasting In Presence Of Gas.—(a) Explain the danger incident to blasting with ordinary black powder in gaseous workings. (b) How is this danger largely overcome in the use of dynamite for blasting? (c) Describe the class of explosives known as flameless powders.

Compare these three forms of explosives and give their relative advantages and disadvantages in blasting coal.

QUES. 623.—Effect Of Placing A Regulator, Power Constant.—A certain fan is maintaining a circulation of 50,000 cubic feet of air in a certain mine in two splits of equal length; split A being 4' x 12', and split B 6' x 12' in cross section and no regulator being used. It is now desired to reduce the quantity of air passing in split B to 20,000 cubic feet by the introduction of a regulator. Assuming that the power upon the air at the point of split remains unchanged, what effect will the placing of this regulator have (a) upon the air passing in the two splits, (b) upon the speed of the fan?

[NOTE.—In assuming that the power applied to the air at the mouth of the splits remains unchanged it is supposed that the splits are at the foot of the downcast shaft, and the resistance of the shafts is ignored; the increased resistance of the fan due to the passage of a larger quantity of air per minute is also ignored, that is to say, it is assumed that the same work is absorbed by the fan when a larger quantity of air is passing, or that the efficiency of the fan remains unchanged.]

QUES. 624.—Setting The Valve Of An Engine.—Describe the manner of setting a valve of an engine. State also in what cases you would use an early cut-off, and give sketch showing the position of the valve at the time of cut-off on the following stroke of the engine.

QUES. 625.—Use Of The Injector For Raising Water From A Shaft.—We have been using an injector at the bottom of the hoisting shaft in our mine for lifting the water from the sump to the surface. The injector is placed at the height of 8 feet above the level of the water in the sump. The steam is supplied through a 2 inch pipe carried down the shaft. The depth of the shaft is 250 feet. We often experience considerable trouble in starting the injector after it has been idle for a few hours. Will you kindly explain the reason for this difficulty? The trouble seems to be that the injector does not catch the water. Explain the correct position and manner of starting the ordinary Harrison steam injector when used for throwing water from the bottom of the shaft to the surface.

QUES. 626.—Surveying, Two Plumb Lines In A Hoisting Shaft.—We have recently sunk a shaft 200 feet in depth to be used as a hoisting shaft. The shaft is 8 feet wide and 18 feet in length, including the pump or manway. After driving the entries back 100 yards from the foot of the shaft we desire to connect the surface survey with the entry sights below. Describe how this may be done in the most accurate manner possible. The main shaft bottom has a width in clear between timbers of 14 feet; the pump or manway is connected with the air course by means of a cross-cut 7 yards in length; the first break through at the shaft bottom is 25 yards from the foot of the shaft. Give sketch showing position of the plumb lines in the shaft and the manner of connecting the surface and underground surveys so as to give entry sights referred to the same meridian as that used upon the surface.

Answers to Questions Which Appeared in the October and Previous Numbers and for Which Prizes Have Been Awarded.

QUES. 612.—Haulage, Load upon Guide Sheaves.—Calculate the load upon the journals of each guide sheave around a curve in a haulage road. The radius of the curve at the center line of track is 48 feet, and the sheaves are set 26 inches from track center, and 4 feet apart, center to center. The tension upon the rope is 6 tons.

ANS.—Referring to the figure, let ab and bd represent the tension in the rope ($6 \times 2,000 = 12,000$ lb.) on each side of the sheave b . Then drawing ac and de to complete the parallelogram of forces, the diagonal be of this parallelogram will represent the resultant of the forces, or the thrust or load upon the journals of the sheave b . Now, let c be the center of the curve of which ab and bd are chords, and draw cf bisecting the chord ab ; draw also ag bisecting be . Then, since the parallelogram is equilateral, ag is perpendicular to be ; and from the similar triangles abg and caf , we have the proportion $bg : ab :: af : ac$. But, by construction, bg is one-half the load on a sheave; and af is one-half the distance between the centers of the sheaves ($\frac{4 \times 12}{2} = 24$ in.)

while ab is the load on the rope (12,000 lb.) and ac is the radius of the curve through the centers of the sheaves ($48 \times 12 - 26 = 550$ in.). Substituting values we have finally for the entire load on the journals of each sheave, denoted by L ,

$$L = 2 \left(\frac{24}{550} \right) \times 12,000 = 1,047.2 + \text{lb.}$$

Prizes were awarded in November issue as follows:

CHAS. E. BOWRON, Birmingham, Ala.

Second Prize.—THEODORE SIMONS, Roseland, B. C.

QUES. 618.—Energy of Fly Wheel.—The fly wheel of an engine measures 6 feet in diameter, out to out, and 8 inches on the face, the thickness of the rim being 3 inches. If this wheel is set upon the crank shaft of a 12" x 16" engine, at what speed will the stored energy of the wheel equal the power of the engine, assuming a mean effective cylinder pressure of 50 pounds per square inch?

Ans.—Let u = foot-pounds of work per second,
 n = mean effective cylinder pressure (lb. per sq. in.),
 l = length of stroke (feet),
 a = area of piston (sq. in.),
 n = number of revolutions per second.

Then, $u = 2 \pi a n = 2 \times 50 \times \frac{1}{2} \times .7854 \times 12^2 \times n = 15,080 n$.
 Since 1 cubic inch of iron weighs .26 pound, the weight of the fly wheel is $.7854 (72^2 - 66^2) \times 8 \times .26 = 1,352.6$ lb.; the outer and inner diameters of the rim being 72 and 66 inches, respectively.

[Supposing the entire mass of the wheel to be concentrated at the center of gravity of the cross section of the rim of the wheel, or to revolve in a circle whose circumference is 3.1416×5.75 = say 18 ft.; the energy of the fly wheel is found as follows:

Let u = energy of fly wheel (foot-pounds per sec.),
 m = mass of wheel considered as concentrated at the center of gravity of the cross section of the rim,
 W = weight of wheel,
 g = force of gravity (32.16),
 v = velocity of center of gravity of rim (ft. per sec.).

Then,

$$u = \frac{mv^2}{2} = \frac{Wv^2}{2g} = \frac{1,352.6 \times (18n)^2}{2 \times 32.16} = 6,813.5 n^2.$$

But the energy of the fly wheel is to equal the power developed by the engine.

Therefore, $6,813.5 n^2 = 15,080 n$, or, $n = \frac{15,080}{6,813.5} = 2.213$

revolutions per second.

Linear velocity of a point at the center of gravity of the section of the fly wheel rim = $2.213 \times 18 = 39.834$ feet per second. J. N. S. WILLIAMS, Honolulu, Hawaiian Islands.

QUES. 620.—*Principle of the Safety Lamp.*—Explain clearly and simply the principle of the safety lamp, or tell in a few plain words what prevents the flame of the gases burning within the lamp from passing through the apertures of the wire gauze.

Ans.—The claim to safety in all so called safety lamps is based upon these lamps being so constructed that the flame under ordinary conditions is prevented from coming in contact with the gaseous atmosphere surrounding the lamp. This is accomplished by enclosing the flame of the lamp within a cylinder of fine wire gauze. It has been found by experiment that a flame will not pass through the small apertures of the cool wire gauze except by increased pressure. [As for example, when the flame is blown by a rapid current of air against the gauze, or when an explosion of gas occurs within the lamp.] The theory is that the gas burning within the lamp as it passes through the wire gauze is divided into little streams of gas by the wires of the gauze, there being 28 wires to the inch. [$28^2 = 784$ openings per square inch.] Each little stream of gas is cooled below the temperature of ignition, by its proximity to the cool gauze. The flame is thereby prevented from passing through the gauze as long as the latter remains cool. The wires of the gauze cool the burning gases by absorbing enough of their heat to reduce the temperature of the burning gases below the temperature necessary for ignition.

Gas will not ignite from a spark or a red hot wire, but requires direct contact with flame; but a red hot gauze will soon allow the passage of the flame of the gas burning within the lamp, and this will ignite the gases outside of the lamp. Therefore, whenever the gauze of a safety lamp becomes hot the lamp must be removed to a pure atmosphere and allowed to cool.

[There is always a thin layer of gas that does not burn, between any cool surface and a flame. The temperature of this thin layer of gas that does not burn, has been lowered, by the absorption of its heat by the cool surface, below the point necessary for the ignition of the gas. Flame does not touch a cool surface.] D. J. LEWIS, Helvetia, Pa.

Second Prize.—THOMAS O'BRIEN, La Salle, Ill.

QUES. 621.—*Measurement of Water Flowing in a Ditch or Flume.* The weir opening of a certain flume is exactly 72 inches in width, and the depth of water flowing over the weir is 5½ inches. Calculate the number of gallons of water flowing over the weir per minute. Desiring to check the measurement of the flow in this flume, a little piece of board was floated upon the surface of the water in the flume, and the time observed that it took to pass between two points 50 feet apart. The observed time was 36 seconds. The full width of the flume in the clear is 90 inches, and the depth of the water 8 inches. Show how closely this latter observation checks the first calculation.

Ans.—Let Q = discharge (cu. ft. per sec.),
 l = length of weir (ft.),
 h = effective head (ft.); that is to say, the vertical distance from the sill over which the water flows to the surface of the still water above the weir.

Then by Francis' formula $Q = 3.33 l \sqrt{h^3}$. Now, if we let Q_1 equal the discharge in cubic feet per minute, and l_1 and h_1 are taken in inches, this formula then becomes $Q_1 = 0.4 l_1 \sqrt{h_1^3}$. Substituting the values given in the question we obtain $Q_1 = 0.4 \times 72 \sqrt{5.25^3} = 346.44$ cu. ft. per min., or, 2,591.4 gal. per min.

To check this we have a float which traverses fifty feet in thirty-six seconds, or, $\frac{50}{36} = 1.389$ feet per second on the surface. But the surface water of a stream flows faster than the water at the bottom or sides, the average velocity being 83 per cent. of the surface velocity at the middle of the stream. Then 83 per cent. of 1.389 equals $.83 \times 1.389 = 1.153$ ft. per sec.; and the quantity of flow is equal to the average velocity times the cross-sectional area of the flume. In this case the cross-sectional area of the flume is $90'' \times 8'' = 720$ sq. in., or 5 sq. ft. And $Q = 1.153 \times 5 = 5.765$ cu. ft. per sec. Then, $5.765 \times 7.48 \times 60 = 2,587.33$ gal. per min., which for all practical purposes checks the first calculation. W. H. SHERBURNE, Cripple Creek, Colo.

Second Prize.—JOSEPH DAVY, Nanaimo, B. C.

QUES. 622.—*Size of Pump.*—Calculate the size of a direct acting pump that will discharge 1,600 gallons of water per minute from a sump at the bottom of a shaft 300 feet deep, assuming the steam cylinder pressure to be 80 pounds per square inch.

Ans.—Assuming for this work a duplex pump, having a piston speed of 100 feet per minute for each cylinder, and assuming an efficiency at the steam end of 75 per cent., and at the water end of say 85 per cent. [This is frequently assumed as only 80 per cent.], and letting

G = amount of discharge (gal. per min.),
 h = height of lift (ft.),
 p = mean effective cylinder pressure (lb. per sq. in.),
 D = diameter of steam cylinder (in.),
 d = diameter of plunger (in.),
 S = piston speed (ft. per min.),

we have, since the weight of a gallon of water is 8½ pounds, for the water end of each pump,

$$8\frac{1}{2} G h = .75 \times 2(p \times .7854 D^2 S);$$

or substituting the values given,
 $8\frac{1}{2} \times 1,600 \times 300 = .75 \times 2 \times 80 \times .7854 \times D^2 \times 100;$
 whence, $D = 20.6$ in.

Again, since there are 231 cubic inches in a gallon, we have,
 $231 G = .85 \times 2(.7854 d^2 S \times 12),$

or substituting the values given, we have,
 $231 \times 1,600 = .85 \times 2 \times .7854 \times d^2 \times 100 \times 12;$
 whence, $d = 15.1$.

We would select the pump of the nearest market size to these dimensions; say for example, a duplex Worthington pump 25'' × 15'' × 15''. [The length of stroke is determined largely by manufacturers, being dependent upon the size of the pump. It is customary to design pumps of moderate lift for a piston speed of 100 feet per minute. As the length of stroke is shorter the pump makes a larger number of strokes per minute and vice versa.]

CHAS. E. BOWRON, Birmingham, Ala.

Second Prize.—JAMES RADFORD, Springfield, Ill.

QUES. 623.—*Force Required to Open a Mine Door.*—Calculate the force required to pull open a mine door at the shaft bottom, between the main intake and return entries of a mine, the water-gauge reading at the door being 3 inches. The size of the door is 5 ft. × 6 ft., and the position of the handle is 5½ feet from the axis of the hinges. The door is assumed to fit snugly and to be practically air-tight.

Ans.—Area of the door = $6 \times 5 = 30$ sq. ft., ventilating pressure, as shown by water gauge reading = $3 \times 5.2 = 15.6$ lb. per sq. ft.; total pressure on door = $30 \times 15.6 = 468$ lb. The center of this pressure is at the center of the door, or 3 feet from the axis of the hinges, while the position of the handle is 5½ feet from the same. Hence, disregarding friction [the moment of the pull exerted on the handle and the moment of the pressure acting at the center of the door will be equal] when the door is about to open, $5\frac{1}{2} \times p = 3 \times 468$, or $p = 255\frac{1}{2}$ lb. Any force greater than this will open the door.

ROBT. PICKETT, Spring Valley, Ill.

Second Prize.—A. B. JESSUP, Centralia, Pa.

QUES. 624.—*Mine Resistance, How Affected by Splitting.*—When the air current passing in a mine is divided into two or more equal splits, is the resistance of the mine thereby diminished or increased, or does it remain the same after the splitting as before, assuming the power upon the air is constant?

Ans.—Splitting the air in a mine does not diminish the resistance when the same power is applied as before splitting. The same power applied to a number of splits as applied to a single aircourse will produce a larger quantity of air. The power producing ventilation in the single aircourse will produce a greater quantity in a series of splits until the resistance in the splits is equal to the resistance of the original airway.

PETER WELSH, Trauger, Pa.

[Out of the large number of answers received from some of our best contestants, in reply to the above question, only one was correct. Some of these answers said the mine resistance would be increased four times when the number of splits was doubled, basing this assumption on the fact that the quantity of air will be proportionate to the number of splits, and the pressure vary as the square of the quantity. This is, of course, careless reasoning; but the majority of the answers assumed that the mine resistance was indicated by the unit of ventilating pressure (p) and since the pressure decreases the mine resistance would be likewise decreased. One contestant came nearer to the correct answer by showing that if the same power were applied to the airways the velocity would remain constant before and after splitting, but then proceeded to show that p , which he called the resistance, varied inversely as the number of splits. Another reply stated rightly that the resistance of the mine was the pressure producing ventilation, but wrongly assumed that this pressure was the unit of ventilating pressure. The resistance of the mine is always equal to the total pressure producing ventilation. This total pressure (pa) is the unit of ventilating pressure p multiplied by the area; and remains constant for a constant power, in splitting, ignoring shaft resistance and supposing the power applied to the splits to remain constant. The expression for the mine resistance is $pa = k s^2$. This is more fully explained in an article "Conditions in Mine Ventilation," on page 234.]

QUES. 625.—Owing to the cut not being in readiness, the publication of the answer to this question is deferred till next month. Prizes have been awarded as follows: First prize, Theodore Simons, Roseland, B. C.; second prize, Fremont Crane, Spokane, Wash.

QUES. 626.—*Acceleration Against Resistance.*—Can acceleration take place against resistance, and, if so, how is the acceleration to be determined? Does the tractive force of an engine accelerate the motion of a train until a uniform speed is attained, and why does it not continue to accelerate always, or what is the limit to the acceleration in such a case?

ANS.—Acceleration *does* take place against resistance. [When an engine or any body moves from a state of rest to a state of uniform motion, acceleration takes place. When uniform motion has been attained the body would continue to move at this rate forever, by virtue of its own inertia and without the further application of force, were it not for the resistance.] The force of the engine maintains its motion in opposition to the resisting forces, such as the friction and the resistance of the air.

Let m = the mass moved;

f = the acceleration due to the effective force, or the force producing motion;

F = the total force (lb.) applied against the resistance;

R = resistance (lb.).

Then, since the *effective force* or the force producing motion is ($F - R$); [and since the measure of this effective force, or the *unit force*, is a force that will produce a unit of velocity in a unit of mass in a unit of time, or a force that will produce a unit of acceleration in a unit of mass], we write,

$$F - R = mf \text{ or } f = \frac{F - R}{m}$$

This is the expression for acceleration. According as the applied force F is greater or less than the resistance R , the acceleration of the constant mass m will be positive or negative. When F is greater than R the acceleration is positive [and there is a gain in velocity]; when F is less than R the acceleration is negative. We observe there are two limits, in the first case *uniform motion*, in the second case *rest*; the acceleration becoming zero, in each case, when $R = F$.

[It is interesting to observe that since the applied force F and the resistance R are given in pounds, they represent ideal masses in opposition; and whichever way motion takes place, according as the force or the resistance is predominant, the total mass moved m , equals $\frac{F+R}{g}$; and substituting this value for m , we have finally for the expression for acceleration against resistance, $f = \frac{F-R}{F+R} \times g$, which expression is identical with the expression given in MINES AND MINERALS, page 522, June, 1900.]

M. B. SPAULDING, New York City.

QUES. 627.—*Arrangement of Shaft Bottom.*—Describe the arrangement of the tracks, manway, pumps, etc. at the bottom of a shaft 250 feet deep, and making 1,200 gallons of water per hour, the output of the shaft being 1,000 tons per day of 10 hours, and all of the pumping to be done in 4 hours or between shifts morning and evening. Give the size of pump, size of shaft, depth of sump, and length and grade of shaft bottoms. Caging is to be done from both sides of the shaft, and arrangements must be made for cross-caging in case of unequal production. The seam is 5 feet thick and has a good roof. Give sketch or plan of shaft bottoms, showing tracks, plates, manways, pumps, etc.

[This question still remains open.—EDITOR.]

The Exeter Noiseless Gravity Conveyor.

One of the greatest changes which has taken place in mining practice within recent years is in connection with the handling of materials upon the surface. Some form of conveyor is now used at nearly every surface works, and in the development and manufacture of such conveyors the Exeter Machine Works, of Pittston, Pa., has taken a prominent part. The following is a description of the essential features of the standard conveyor as made by this company:

The chain is constructed of drop forged steel links with eyes reinforced and enlarged, thus giving increased strength and wearing surface. A heavy steel bushing or sleeve passes through the links and a steel pin through the sleeve. The wheels rest upon the sleeves and are self-lubricating; the wearing and friction being reduced to a minimum. The buckets are made of pressed sheet steel and are extra heavy. The dumping arrangement is perfectly smooth in its operation, the bucket discharging the load in the opposite direction to the movement of the conveyor.

The loader is another noticeable feature of this conveyor, simple in its operation, and perfectly accomplishing the purpose for which it is intended. It consists of an endless chain carrying V caps; the spaces corresponding to the spaces between the buckets and fitting closely over the edges of the bucket it forms an absolutely endless trough at the loading point. The loader is made either stationary or portable, or, if there are several loading points to be used simultaneously, the loader can be made of sufficient length to reach these different points.

The conveyor is driven by sprocket wheels engaging with the wheels of the chain. All sprockets are made of steel casting and at all angles steel banded traction wheels are employed. All parts of the conveyor are made extra heavy and workmanship and material are first class in every respect.

The Exeter Machine Works are at present installing this system at the 29th St. Station of the New York Gas, Electric Light, Heat & Power Co., and will be glad to furnish more complete details to interested parties.

Central Mining Institute of Western Pennsylvania.

The winter meeting of the Central Mining Institute of Western Pennsylvania will be held in the Court House, Pittsburgh, Wednesday and Thursday, December 19th and 20th. The following has been announced as a provisional program:

FORENOON SESSION, DEC. 19, 1900, 10 O'CLOCK A. M.

1. Minutes of last meeting.
2. Unfinished business.
3. New business.
4. Presidential address—T. B. DeArmit.
5. Election of officers.

AFTERNOON SESSION, DEC. 19, 1:30 P. M.

6. Paper—On Mine Management and Some of its Responsibilities, by Wm. Seddon, Supt. of Mines, Brownsville, Pa.
7. Paper—Would the Establishment of a National Bureau of Mines at Washington Conduce to the Advancement of the Science of Mining Methods and Promote the Interests of the Mining Industry in General, and be of benefit to the Public? by H. H. Stock, editor of MINES AND MINERALS, Scranton, Pa.

FORENOON SESSION, DEC. 20, 1900, 9 A. M.

8. Address—By Alex. Dempster, M. E., Pittsburg, Pa.
9. Paper—Can the Present Mining Methods, (now in general practice) of the Thick Vein District, Pittsburg Coal Field, be Improved Upon? by Joseph Blower, Supt. of Mines, West Brownsville, Pa.

AFTERNOON SESSION, DEC. 20, 1:30 P. M.

10. Paper—On the System of Underground Haulage and Methods of Mining as Installed and in Use at the Windber Mines, by J. S. Cunningham, Supt. of Mines, Windber, Pa.
11. Paper—On the Gasoline Locomotive as a Factor in Mine Haulage, by F. C. Keighley, Supt. of Mines, Uniontown, Pa.

Cement Flumes.

The cement flumes built by the Arroyo Flume & Ditch Company, Los Angeles, Cal., last spring have proved to be such a success that others will undoubtedly be constructed along the ditches of the company's system, which embraces a large acreage in the vicinity of Downey, California. The company spent about \$20,000 on the flumes built last spring. It is now proposed to spend \$10,000 in extending the flumes. In the cement flumes there has been practically no trouble from obstructions caused by weeds and other articles as in the dirt ditches, and the flow in the cement flumes is said to be even more rapid than in the wooden ones.—*Cement and Slate.*

ENDLESS ROPE HAULAGE

At the Pratt Mines of the Tennessee Coal, Iron and Railroad Company at Ensley, Alabama.*

The following is a description of a new system of endless rope haulage installed at the new slope No. 3 Pratt coal mine of the Tennessee Coal, Iron & Railroad Co. at Ensley, Alabama. It was designed and its details worked out by Erskine Ramsay, chief engineer of the company, whose early experience in coal mining and coke making was in the Connellsville region of Pennsylvania. The plant in question was put in to replace the old arrangements at plants at Slope No. 3, which at the outset were intended to exhaust this particular part of the coal field. The economies possible under the new system are such that the decision to make the expenditure for its installation was readily made.

The Pratt seam is the principal seam in the Warrior coal field, being practically coincident with it and lying near the top of the coal measures. It is underlaid by other well-known seams, as the Double, the New Castle and the Blue Creek. The mines are mostly opened upon the outcrop of the seam, following it down

ENDLESS ROPE HAULAGE, PRATT MINES, ENSLEY, ALA.

on the pitch, which is from 15 to 25 per cent., to the basin or more level part of the seam, this being from 1,000 to 2,000 feet from the outcrop. The Warrior coal field has been the backbone of the Birmingham district since the demonstration of the fact that this coal would make a furnace coke second only to Connellsville, being at the same time a steam and domestic coal of excellent quality. The old opening was of the slope type, as is also the new, the slope being opened on the outcrop of the coal and following it down. The grade at the outcrop was about 15 degrees, which flattened considerably, and so much so that when the slope had reached a point about 1,200 feet from the outcrop the pitch was so reduced that the mine cars would no longer drop by gravity into the mines and pull the rope after them. This necessitated at this point the introduction of another engine to haul the coal from interior points in the mine to the foot of the slope, from which point it was hauled by the outside engine on to the tippie. This rehandling was expensive and besides kept the output of the mine down to a maximum of about 700 tons a day of nine hours' work.

Features of the New System.—As the field of coal is quite large it was determined to put in a new hoisting plant and use, instead of the old slope or engine plane system, the newer over-

head endless rope system, and with this object in view an opening was made at the outcrop about 100 feet west of the old opening and the direction was changed so as to put the new haulageway on about the line of the greatest dip of the coal seam. This new haulage road or slope ran through quite a portion of the old workings of the mine and intersected some of the existing haulage roads, but with the exception of 300 or 400 feet near the outcrop there was no great difficulty encountered in putting through the new haulage road. The new slope or haulage road was made double-track and laid with 40-lb. rails, and to begin with the inside terminus of the haulage was fixed at a point about 4,000 feet from the tippie, the idea being to extend the haulage from time to time as the workings of the mine advanced. The elevation of the bull wheel or return sheave in the mine is 313 feet above sea level and at the tippie it is 586 feet, the maximum grade being about 15 per cent. and located near the pit mouth.

The general arrangement of the engine driving the haulage machinery is shown in Fig. 2. This is an 18" X 42" single Corliss engine, and it is belted to the rope driving mechanism which is of much the same pattern and general design as the cable road appliances used in some cities. It will be noted that both drums are driven. The engine itself is connected in such a way as

to be thrown out of gear with a friction clutch, thus stopping the rope almost instantly when a signal is given from any point along the haulage road in the interior of the mine. These signals are given over a system of electric apparatus consisting of two wires strung along the entire length of the haulage road and separated about 8 inches, the signals being given from any point by pressing the wires together or connecting them by a "steel" which is carried ordinarily by the chainers who hook on the cars to the rope, and whenever the wires are connected the vibrating bell rings in the engine room. The batteries and other apparatus are located in the engine room. One wire of the signaling apparatus is utilized for telephone purposes, the phones being located in the engine room and at several points along the haulageway. This is done to furnish almost instantaneous communication between the outside and various points in the mine when from accident or other cause it becomes desirable.

The empty cars going in and the loaded cars coming out are attached singly or in pairs to the rope at intervals of from 100 to 200 feet, depending, of course, upon the amount of coal which it is required to haul.

The rope travels at the rate of 158 feet per minute and delivers to the tippie a constant stream of loaded cars which are dumped onto the screens or into the railroad cars as they are delivered from the rope.

Method of Attaching Cars to the Rope.—In the mine the cars are attached at the various landings or headings by simply raising the rope and allowing the cars to run underneath by gravity, the rope being guided into a V-shaped automatic clutch "grip" or "grab." The empties are taken off by simply raising the rope and placing it in a pulley fixed overhead in the roof, and as the cars come along, the rope gradually and automatically lifts out of the "grab," releasing the car, and it passes off the main line into the switches or side-tracks by gravity. The "grabs" or clutches are shown in detail in Fig. 3. These "grabs," as is shown, fit into two sockets on the rear end of the car, the motion of the rope and the friction of the same in the "grab" causing the latter to turn slightly sideways and firmly grip the rope, the tightness of the grip on the rope depending upon the grade of the track. The heavier the grade the firmer will the "grab" take hold of the rope. These "grabs" hang and are free to turn in the sockets in either direction, so that they either pull the car when going up grade or hold it back when going down grade.

When the cars reach the tippie they are automatically released

* Reprinted through the courtesy of The Iron Trade Review.

by a reversal of the grade, together with the gradual ascent of the rope to the sheave, which holds the rope in a fixed position. The cars then run by gravity to the dump and are returned to the empty track on the other side on a down grade, the rope being guided into the "grab" when the car starts off on another trip into the mine.

The rope when not carried by the cars runs on rollers placed in the center of the tracks for that purpose, but practically all of the time the rope is suspended by the cars at points of say 100 to 200 feet apart and does not sag enough to allow it to drag on the track or run on the rollers. This feature of the endless rope system described is different from that generally put in, as most mines carry the rope on rollers continuously, as it runs underneath the cars. This causes considerable wear and tear on the rope and renders necessary a constant renewal of the rollers. With the Pratt mine plant there is practically no wear on the rope except at either end of the haulage where it passes around, in one case the drums of the driving mechanism, or in the other case the bull wheel or sheave at the terminus of the haulage in the mine.

Advantages of Endless Rope Haulage.—The application of the endless rope haulage, such as the Tennessee company uses, to the hauling of coal in the mines is rather novel in this country, as is also the plan of hauling the coal direct from the interior of the mine at the various stations or landings along the haulage, up the slope and onto the tippie to be dumped from the mine cars ready for shipment. Some of the advantages of the system may be thus summarized: (a) Continuous and steady output of coal regardless of length of haulage. (b) Minimum engine power and steam consumption. (c) The long life of the cars and rope. (d) Minimum risk of accident to life and property. (e) Low cost of operation. The output of the present plant at Slope No. 3 is 1,200 tons, as compared with 700 tons by the old.

This same system of rope haulage is now in use by the

FIG. 2.

Tennessee Coal, Iron & Railroad Co. for delivering coal to the railroad tipples at Slopes Nos. 6 and 7, and is in course of installation at Slope No. 10 at Pratt mines. It is altogether certain that this particular haulage at slope No. 3 which we have described will be extended three or four miles, and while the main haulage will continue to be on a tangent it is possible, and is now a practice in some of the company's mines, to run a loop from the same rope into the side headings where they are very long and the haulage is expensive.

A prime feature of this plan of hauling coal as compared with the ordinary endless rope, or the more prevalent tail rope system, in both of which the cars are hauled in trips, is that no matter how long the haulage is, the capacity to deliver coal at the tippie is in no manner reduced. The coal will be delivered there just as fast as it is attached to the rope at the various stations, but of course the longer the haulage is, with a given distance between the cars the greater will be the total number of cars attached to the rope at any one time.

The life of the cars and rope is very much increased by this system. All of the moving parts run so slowly as to reduce to the minimum the usual wear and tear, which on long haulages of the usual type hauling in trips where high speeds are necessary to obtain the output, is quite excessive. Further, everything moves so slowly there is practically no danger of the cars overtaking a man who might happen to be traveling on the track. This system is capable of hauling over grades which would preclude the use of electric motors, and where the haul is quite long, as is the case in some of the Alabama mines, a great number of motors would be required and it would be necessary to run at high rates of speed to obtain the required output. No men ride with the cars as they are being hauled out and in, as is usual

where rope riders are employed, the only labor required being that necessary to attach the empty car as it is sent into the mines and the loaded car as it starts out. The cars take care of themselves while on the journey, which at Slope No. 3 requires about half an hour from mine to tippie.

Referring to Fig. 2, which shows the arrangement of engine and drums, the following details will be interesting, in addition to

FIG. 3.

those given above: The diameters of the 20-inch pulleys are 3 feet and 7 feet for the engine shaft and pinion shaft respectively. The rope drums are 72 inches diameter, the spur gear wheel 72 inches and the pinion 18 inches. The initial steam pressure is 80 pounds and the mean effective steam pressure when the engine is working under load, 19 pounds; corresponding cut off, about 11 per cent.; revolutions of engine per minute, 68. The average horsepower developed, as shown by indicator cards, with the engine working under load is 69½. The rope, which is of 1-inch diameter, has a speed of 158 feet a minute. The average weight of empty mine cars is 1,276 pounds, and of the coal in loaded mine cars, 3,000 pounds, making the total weight of loaded mine cars, 4,476 pounds.

The Lunkenheimer Automatic Injector.

The illustration here given shows a sectional view of an automatic injector made by the well known firm, The Lunkenheimer Company, of Cincinnati, Ohio, and Denver, Colo. This injector is said to be absolutely automatic at all times, so that it can be relied upon to restart instantly after a temporary interruption of either the steam or water supply.

The exterior of the injector is heavily enameled giving it a very pleasing appearance, and all parts of the apparatus are well proportioned and made with due regard to durability. The body is of cast iron, and the tubes of a specially hard bronze composition made expressly for the purpose. The internal areas of these tubes are smaller than some other forms of injector of equal capacity; hence they will not wear out so quickly, but all tubes and wearing parts can be easily renewed at slight expense if worn. The tubes are all screwed into place and do not depend upon tight unions to secure them.

The Lunkenheimer Company issues a circular fully descriptive of this injector which explains in detail the method of setting it up, and would be pleased to send it to any interested party.

Sale of Claims.

The Government at Ottawa, it is reported, will offer for sale at public auction in Dawson every claim that has reverted to it by lapse or otherwise, and thirty days thereafter all claims not sold will be declared open for location.

FARNCOMB HILL GOLD DEPOSITS.

A Description of the Rich and Peculiar Deposits and Methods of Working Them Near Breckenridge, Colorado.

Written for MINES AND MINERALS, by Prof. Arthur Lakes.

The gold deposits of Farncomb Hill, near Breckenridge, Colorado, are amongst the most remarkable in the West. The hill has long been celebrated for the beautiful specimens of flagré crystallized gold that have found their way into many museums in the country. Some millions in gold have also been extracted during a period of many years from this hill and its surroundings. The hill lies about five miles east of Breckenridge up French Gulch, celebrated in past years for its extensive placer deposits. All the way up the Gulch on the south side we see evidences of the extensive mining that took place in the "fifties," and is still being carried on. The banks of yellow gravel upwards of 100 feet deep are profusely channeled on the south bank by old and primitive sluicings which are being succeeded now by the newest and latest methods of hydraulic mining. These glacial placer deposits cover a large area and have a considerable thickness on the flanks of Mt. Baldy and Mt. Guyot. On the opposite or north side are several mines, such as the "Oro," which in silver days were good producers of lead and silver. There was quite a village at one time at what is known now as Lincoln.

The formations on the north side appear to differ from those on the south, being mainly sandstones of Cretaceous and Mesozoic age, metamorphosed into quartzites, and traversed by numerous dykes of porphyrite containing large crystals of orthoclase feldspar.

Just beyond French Flat and the Lincoln Mine the strata alter and become of great thickness, including several thousands of feet of black Marine Cretaceous shales, traversed by a few dykes of porphyrite. This is the formation which constitutes Farncomb Hill and in numerous minute veins or veinlets in these shales the celebrated specimens of gold ore have been found.

We ascend the hill by a steep well-graded road cut in the shales, and at the top find the Ontario Mine where a great deal of gold has been extracted from pockets and veinlets in the shale. Descending the opposite slope of the hill for some 600 feet we find the steep hillside of black shale penetrated by the numerous tunnels of the Wapiti Mine.

The principal veins on which these tunnels are located lie in the shale, with dykes of porphyry a few yards on either side. The dip of the shale is about 25 degrees and to the northeast nearly the whole black face of the hill has been scored by hydraulicking. Near the summit a flume runs for thirteen miles on a high line towards its source in the distant hills near Montezuma and Swandyke in the Continental Divide. From this flume, pipes with nozzles attached descend into the valley below, carrying water with enormous power and over 300 feet of head. At the bottom of the hill is a placer of considerable extent, the material having been derived from the detritus of Farncomb Hill.

Wherever prospecting has been done along the hill it has been by letting out sluice-water at intervals from the high line ditch and by booming, i. e., cutting a swath by a sudden rush of water down the mountain side through the loose detritus to bed rock shale. Two modes of mining have also been extensively followed, one that of mining by tunnels on the vein and across them, the length of these tunnels now aggregating about five miles, the other by booming and washing the surface and by hydraulic placer mining. The veins or veinlets containing the gold run in a series of minute cracks or cleavage planes, cutting the mountain from northeast to southwest. These steep fissures are also traversed by a flatter transverse set from southeast to northwest. The latter set are not so gold-bearing as the former, but rich pockets of ore are occasionally met at the point where the two intersect. The fine seams or fissures often contain a talcose soft substance very rich in gold, and calcite also occurs. At other places the vein consists of a narrow veinlet not more than half an inch wide of copper pyrite and iron, also carrying gold. The commoner occurrence is to find the fine knife-blade seam lined with fine gold, sometimes for several feet, as if it had been plastered or frescoed on the slate wall. The gold occurs in fine wires and in broad crystalline flakes and scales often of great beauty. Lead often occurs in the veinlets entwined with gold wire. All the gold is free milling, even that in the bodies of copper pyrite and iron. The free gold is carefully scraped off the walls. When contained in the pyrite gouge or wall rock it is treated with a Huntington mill.

There are a great number of veinlets scattered through the formation. In a width of upwards of half a mile of shale worked, as many as 50 veins are well known and others are doubtless as yet undiscovered. The veinlets are so small, often no thicker than a knife-blade, and so pockety is the ore, that it takes an experienced man to follow them into the hill. Occasional rich

pockets of ore have been found enclosed in the porphyry itself. A single pocket has often yielded many thousands of dollars of ore obtained in a few hours or days. One pocket alone yielded \$29,000 in a very short time. A certain "talcose" seam has also been a great yielder.

Quite as much work has been done on the outside of the hill by fluming, booming and hydraulicking and perhaps nearly as much wealth obtained as by mining by tunnels inside the hill. These outside surface values are found by washing the hill-side detritus and are mainly derived from the "overflow" or outcrops of the veins. Rich pannings are found where these outcrops occur, while a few yards on either side of them the ground may be barren. It is a difficult ground to prospect because the indications of such minute veinlets on the surface are rarely visible, almost all has to be done by a careful system of panning and subsequent booming or hydraulicking, a vein found can then be followed down with some degree of certainty. The mountain has been penetrated over 1,000 feet by tunnels which have a vertical depth of 300 feet. The gold found in the so-called placer below is like that found in the vein, viz.: crystalline in form, as if but little removed from its source, while that found in neighboring gulches coming down the other branches of the Swan River from Swandyke and Montezuma is water worn. At the confluence of these ravines in a little park there was in the days of "59" a camp of over 2,000 men, called "Parkville," and a great deal of rich placer gold and many large gold nuggets were obtained. In sluicing and hydraulicking over that section recently silver two-cent pieces of 1850 date are found, together with numerous Indian arrow-heads. The place was at one time defended by a stockade against the Indians. Into this park drains the waters of the new gold camp of Swandyke. In hydraulicking this slaty detritus in the placers, a steep grade and rapid and continuous flow of water are needed on account of the flatness of the slates tending to clog. A grade of from 8 to 10 inches is used, the sluices being 2 feet wide with block riffles.

The origin of this remarkable gold deposit is probably that suggested by the late Professor Eggleston, viz.: that the gold was either in solution or vaporized or sublimated condition when it ascended through these minute lines of least resistance and was precipitated and crystallized upon the walls of the fissures. The heat agencies were doubtless connected with the eruption of the dikes of porphyrite penetrating the hill, and quite rich deposits of gold have been found in the porphyrites, implying indirectly the source of the metal.

As the upturned and partially metamorphosed Cretaceous shales, traversed by identically the same porphyrite rocks as at Farncomb hill, are quite a characteristic feature of the Breckenridge region we see no reason why similar deposits of gold under similar conditions might not be found in that district by judicious prospecting and booming.

India Rubber.

More than a hundred million dollars' worth of india rubber has been imported into the United States during the past four years, and more than sixty million dollars' worth in the last two years. A decade ago the annual importations of india rubber amounted to about \$15,000,000; now they exceed \$30,000,000, and are steadily increasing. Practically all of the importations of rubber come in crude form for use of manufacturers, who are constantly extending its application to various new lines of industry. Northern Brazil, Southern Mexico, the West Indies, Central Africa, India, the Straits Settlements, and the Dutch East Indies supply this increasingly important feature of our importations. Probably no single article has made a more rapid growth in its relations to manufactures, and consequently commerce, in the past few years than rubber. As a consequence attention is now being given to the cultivation and systematic production of the various plants and trees from which it can be produced.

India rubber is not, as is generally supposed, the product of a single tree, but on the contrary is produced from a variety of trees and plants. Some of these flourish only in a moist soil and atmosphere, while others thrive on stony soil, provided they receive ample though intermittent rainfall; though in all cases a tropical or subtropical climate is requisite. Most of the india rubber of South and Central America and India is from trees, but in the islands of the Indian archipelago, the supply of rubber is chiefly from a gigantic creeper, which in five years' growth attains a length of 200 feet and from 20 to 30 inches in circumference, and which yields annually from 50 to 60 pounds of caoutchouc. Java, Sumatra, Penang, Singapore, and French Indo China are already large producers of crude india rubber, or caoutchouc, and its production in the West Indies has been sufficient to indicate the entire practicability of its being made an important industry in Cuba and Porto Rico, as well as in the Hawaiian, Philippine and Samoan Islands.

TRADE NOTICES.

The Bullock Mfg. Co., of Chicago Ill., has received a gold medal at the Paris Exposition for its diamond drills.

The Macomber & Whyte Rope Company, Chicago, Ill., has issued a very neat pictorial business card advertising its wire rope and other specialties.

The Bethlehem Steel Co., of South Bethlehem, Pa., has again opened an office in St. Louis at 930 N. Main St. in charge of Mr. S. E. Freeman.

The Bethlehem Steel Company, of South Bethlehem Pa., has appointed the Abner Doble Company, Fremont and Howard Streets, San Francisco, its agents for the Pacific Coast.

The 6 H. P. Mietz & Weiss gas engine and 4 H. P. direct connected kerosene engine and electric generator has been awarded the Silver Medal at the Paris Exposition, 1900.

The American Tin Plate Co., of Chicago, Ill., has repeatedly duplicated its orders for Cross oil filters and is now using 19 filters in its plant, which speaks well for the popularity of the Cross filter.

"Bethlehem" forgings have again scored in the remarkable results attained in the trial trips of U. S. battleship Wisconsin and Russian Cruiser Variag. The Wisconsin's shafts were forged from fluid-compressed nickel-steel, and those for the Variag from fluid-compressed carbon steel, all being shaped under the hydraulic press, carefully annealed, and finished according to standard practice.

Mr. Jos. H. Williamson, who for nearly eighteen years has been the business manager of the Manufacturers Advertising Agency, New York City, has severed his relationship with that company to connect himself with the old established Viennet Advertising Agency, 524 Walnut Street, Philadelphia, as its business manager in the place of Mr. Thompson, resigned.

The Link-Belt Engineering Co., of Nicetown, Philadelphia, has found its steadily increasing business requires the opening of an office at Pittsburg. It has accordingly opened one at 1501-2 Park Building, with Mr. T. Frank Webster, Link-Belt Engineer, in charge. Mr. Webster will have the care of all business in that vicinity for this company.

The Listie Mining & Mfg. Co., of Somerset, Pa., have installed an Ottumwa box car loader at their mines. This insures them increased business from parties who want their coal loaded in box cars, as it is claimed for this loader that it does not break and smash the coal, as is done when box cars are loaded by hand. It is claimed the machine has a capacity of 125 tons per hour.

In the second hand department of this issue, J. S. Mundy, Newark, N. J., manufacturer of hoisting engines, advertises a hoisting engine which ought to be of interest to any mine owner who wants a first class article at a very low price. The engine was shipped through an error, and was used only about two weeks, and returned to the manufacturer. It has been all cleaned up, and is in as good condition as when new, and thoroughly guaranteed.

The Bignall & Keeler Mfg. Co., Edwardsville, Ill., manufacturers of Peerless and Duplex Pipe Threading and Cutting Machines, report an excellent run of business. Among recent sales of their specialty are those made to the Tri-Mountain Mining Co., Houghton, Mich.; Aermotor Co., Chicago, (6); Mark Mfg. Co., Chicago; P. C. C. & St. L. Ry. Co.; Pullman Car Co.; United States Naval Academy, Annapolis, (one Duplex 16 in. machine with electric motor direct connected); Ohio Hospital for Epileptics, Gallipolis.

One of the most wonderful growths in the mining supply business has been achieved by the S. H. Supply Co., of Denver, Colo. In two years they have built a business to a point where they have no competition in their lines. New material is sold by them at less than the wholesale prices and second hand goods are valued entirely as to their conditions. They conceived the idea of buying complete plants, dismantling them, placing their material in first class condition, where it will be guaranteed to do the service claimed for it. In addition to this their purchases from sheriff's sales of new goods keep their stock to a point where in amounts it is not equalled by any house in Colorado. It will certainly be of advantage to get their latest catalogue, which is issued every two months, and fully describes the stock they carry.

The Ludlow-Saylor Wire Company, of St. Louis, is rapidly equipping itself to take care of a large amount of new business.

The company is about completing new factory buildings upon a site having a frontage of 200 feet on the Wabash Railroad, and a depth of 500 feet. The main building is 200 by 75 feet, and to this will be added later an L wing 225 by 75 feet. The building is heated by exhaust steam, and the water supply comes from a deep well, thus rendering the plant independent of the city water supply. Of the basement or first floor of the main building 75 x 150 feet will be devoted entirely to machinery for the manufacture of "perfect" double crimped mining cloth. These machines will be disposed in groups of three, each group to be driven by a 15 horsepower motor. The second floor is at present devoted to warehouse use, an extensive stock of wire fencing, barbed wire, plain wire, wire nails, etc., being carried. On the third floor there are now in operation power looms for the weaving of evaporator cloth, mill screen and the finer grades of mining cloth.

We have received the following communication from the Jackson Drill and Manufacturing Company, 756 Larimer street, Denver, Colorado, U. S. A.

DENVER, COLO., Nov. 8, 1900.

Mines and Minerals, Scranton, Pa.:

DEAR SIR:—All persons are notified that the Agreement of License from the Jackson Drill and Manufacturing Company, Denver, Colo., U. S. A., sole owners, for the manufacture and sale of the Jackson Hand Power Rock Drill, in Eastern United States and foreign countries, heretofore held by the Thornton N. Motley Co. (inc.), 48 John street, New York City, is terminated.

All persons are cautioned not to manufacture these drills; nor to purchase them, excepting directly from us or our authorized agents.

All unauthorized manufacture, sale or use will be promptly prosecuted.

THE JACKSON DRILL AND MANUFACTURING CO.,
by J. J. Crippen, V.-Pres't.

The Frank S. De Ronde Co., 52-54 John St., New York, with Branch Office and Warehouse at 48 N. 4th St., Philadelphia, calls special attention to its Federal Boiler Compound and De Ronde's Belt Dressing, both of these products having met with great favor wherever introduced, and especially throughout Pennsylvania in the mining districts. The company offers to send good sized practical working samples of these goods free of charge, or to ship these goods out subject to approval, to any responsible concern. It would pay all those interested to write direct to the company and procure samples of these products. The Frank S. De Ronde Co. is also general distributing agent throughout Pennsylvania for the well known P. & B. Ruberoid Roofing and all other P. & B. products, carrying a full stock of same at the Philadelphia warehouse, from where it is prepared to make prompt shipments. Ruberoid is now and has for many years, been in general use in and about mines, for roofing, covering pipes and hosts of other purposes. This roofing is absolutely water, acid and alkali proof, free from tar and asphalt, strong and very durable. It is also in extensive use by almost every large steam railroad in the country. Those who have not received the large sample books of Ruberoid Roofing should send for copy of same, which will be gladly furnished on application.

The steam plants in the State of Ohio are being rapidly equipped with low water alarms in conformity with a recent enactment of the Legislature of that State. A large number of these devices sprang up to take advantage of the requirement, but it was soon demonstrated that the majority of the manufacturers, recognizing the wisdom of placing the safety of their plants in the keeping of devices that have been tested and not found wanting, would only consider bona fide safety water columns of recognized merit and proven ability. The extreme simplicity of the Pittsburgh Safety Water Column, manufactured by the Pittsburgh Gage & Supply Co., Pittsburgh, Pa., combined with its absolute reliability under any and all conditions to which it may be subjected, easily made it a favorite with steam users who wished to throw about their plants the mantle of protection, that can be relied upon first, last, and all the time. The Pittsburgh Gage & Supply Company planned and executed a brilliant and energetic campaign in Ohio in behalf of their safety water column, which has proved eminently successful. The company had such implicit faith in the superiority of the Pittsburgh Column as a safety and saving device, and that this superiority would be recognized by steam users when brought to their attention, that early in the season the factory was put in operation day and night, and the result of this well planned and executed campaign shows the wisdom of their action. The surplus stock thus accumulated has enabled the flood of orders to be taken care of with reasonable promptness, and already some 1,500 Pittsburgh Safety Water Columns have been installed in Ohio alone, comprising hundreds of prominent concerns ordering a large number of columns each, among which are the following: American Sheet Steel Co., 95; American Steel & Wire Co., 72; Lake Shore & Mich. So. Ry., 80; American Steel Hoop Co., 61; Crown Fire Clay Co., 24; Structural Steel & Iron Works, 20; Ohio Steel Co., 20; Fleischman Company, 12; Erhart & Company, 12; Cincinnati Water Works, 12; Youngstown Steel Co., 10; Hoover & Allison Co., 10.

All this was derived from oxidization of the original massive pyrite. The deposit lay between a greenish quartzite and an overlying sheet of intrusive red syenite consisting of red orthoclase feldspar sprinkled with black crystals of hornblende. A few assays taken of both the pyrite and iron oxide showed the values to be too low grade for profit.

As a practical suggestion to a prospector or miner who may come across such kinds of deposits we may offer the following considerations, which occurred to us at the time:

First.—What shall we do with the massive pyrite? What treatment is it adapted to? Clearly it is not a concentrating

proposition, because it is already concentrated and there is no quartz or gangue matter with it. It is a solid mass of uniform mineral. It is a case of either smelting, or cyaniding, or chlorination. Therefore it must either be shipped to a smelter, or a cyanide mill must be established at the foot of the mountain. The ordi-

MODE OF FORMATION, OXIDATION, AND ENRICHMENT OF MANCOS AND SIMILAR CONTACTS.

nary stamp and concentrating plant already located there could do nothing for such ore. Pyritic smelting by the Austin process would be also unavailable, because of the absence of copper in the deposit, and in the immediate vicinity. Silica, essential to this process, could be, it is true, mechanically supplied although absent in this pyrite deposit. The pyrite ore, supposing it to have sufficient value, is a clear case of ordinary smelting (i. e., apart from the other processes).

Then the question comes—is there value enough to pay for shipping and treatment from this locality?

The oxidized ores on the other hand, provided they carry sufficient values, are presumably free milling ores and could be treated perhaps at the mill 2,000 ft. below, down the steep mountain.

The question of values will have to be determined by assay and mill run and by far deeper development than a 10 ft. prospect hole before such works as a necessary 4,000 ft. long, bucket-tramway be erected down to the present mill. Such a tramway would be a necessity, because a large low grade proposition at this great height would infallibly have to be operated in this way and on a large scale to succeed.

We examined another deposit at a lower level, and more accessible to the mill. Here a big brown oxidized outcrop, about 8 ft. thick, appeared on the side of the cliff close to a dyke of diorite. In this case a hole some 8 or 10 ft. deep showed the thickness of the whole outcrop, for that depth, to be well oxidized and entirely honeycombed, with comparatively little pyrite showing. Mingled with this oxidized gossan was a good deal of bright micaceous iron ore, or specular iron in flakes, a secondary product after oxidization and metamorphism. Even this well oxidized mass gave very disappointing assays, but might prove better with greater depth, as at Mancos.

A third deposit was of a somewhat different character from the others. In this case there was no sedimentary rock present, but a thick horizontal sheet of intrusive diorite had, for a considerable distance, been impregnated by mineral solutions presenting the appearance of a large brown rusty bank, cut by a narrow canyon, down which descended a waterfall from the snow-fed amphitheatre in the mountains above.

This big brown patch early attracted the prospector's attention and on the strength of its possible values, a large mill was erected close to it with abundant water power to run it. An open cut, made for some distance through this brown mass, showed the volcanic rock to be in layers which dipped upwards into the hill. This inclination we believe was caused by the bending downward tendency of rocks on the steep slope of the hill, a not uncommon occurrence with rocks outcropping on steep hill sides. The cut showed that the rocks were here and there spattered with small irregular patches of pyrite, too irregularly scattered, as a rule, to concentrate, except on a very large scale. Assays unfortunately showed this pyrite to be very low grade. Better values were found in the brown oxide, but this proved to be only a thin coating of the layers of porphyry and disappeared entirely at a few feet in depth.

In one portion, however, of this deposit was a shearage zone or possibly a dyke, which was especially oxidized and was traceable, by its brown rusty color, for a few hundred feet across the waterfall ravine. Values in this were fairly good, but a tunnel run in about 50 ft. below it found this zone or dyke, with its parallel vertical shearage planes, to pass into hard diorite, barren, except for a narrow streak of iron pyrite, which, as before, proved valueless. What values there were, were in the oxidized material

only, and this was proved to be only superficial and not enough of it to keep a large mill going for any length of time.

We have been particular with these instances because similar propositions may often occur to the miner, prospector, mine speculator or mine buyer, and it may make a man look before he leaps, and see the various considerations that may be in the way of what at first sight may appear to be a very likely and attractive property.

In a subsequent article we shall give a description of some other cave deposits and peculiar mines.

Phosphate Rock.

The phosphate-rock industry in 1899 was marked by considerable increases in production in Florida and Tennessee, decreased production in South Carolina, a notable advance in the values of Tennessee rock, and the beginning of a phosphate-mining industry in Pennsylvania. In Florida the increase in production was shared by the miners of hard rock, land pebble, and river pebble. No production of soft rock was reported in either 1898 or 1899. The decrease in South Carolina was in the production of land rock, which fell off nearly 75,000 tons, and was only partly made up by an increase of over 30,000 tons in the production of river rock. Tennessee's production increased 37½ per cent. Pennsylvania entered the phosphate industry with an output of 2,000 tons.

A New Throttle Valve.

The Pendry balanced throttle valve, shown in section in the accompanying cut, is particularly well adapted for use on hoisting engines, marine engines, steam shovels, and on all quick-acting engines, as by means of it the full boiler pressure can be instantly admitted to the cylinders and as instantly shut off. In addition to its quick opening feature it is also a perfectly balanced valve, and so can be very easily operated no matter how great the steam pressure being used.

Its operation is as follows: The stem *A* forms two seats with the main valve *B*, one at its upper and one at its lower end. The first slight movement of the handle will raise the stem *A* off its upper seat. The steam passes in through this opening, down through the body of the valve *B* in the space around the stem, and into the balancing chamber *E* through the openings marked *F* on the small sectional view of the valve body to the right. In this way the full boiler pressure is admitted into the chamber *E*, balancing the valve, and as the same pressure is below as above it, it is very easily operated.

It should also be remembered that while this valve is primarily a quick opening one, it can be opened as slowly and as

SECTIONAL VIEW.

gradually as a screw stem valve, and it will stay open at any point you may desire to set it. This feature makes it adapted for use on all types of steam engines. The question of leakage can also be prevented in this valve, as it has but one seat and this can be ground same as that of a globe valve. Circular giving full description may be had by addressing the manufacturers, The Detroit Lubricator Co., Detroit, Mich.

ELECTRIC LOCOMOTIVES.

Principles Which Determine the Size and Power of Locomotives Necessary for Various Loads and Grades.

Written for MINES AND MINERALS, by H. K. Myers, C. E.

Electric locomotives have proven more popular than compressed air, principally because they are more compact and can be used in thin seams without expensive enlargement of gangways.

The vital point in their use is in not overloading them for a long period of time. The motors as constructed at the present time by the best manufacturers are in reality a wonder—while they have a certain horsepower rating based in general on their ability to do given work continuously for 1 hour yet for very short periods this work may be increased 100%. While horsepower rating is universal, yet it is misleading and the proper way should be "draw bar pull" at given speeds.

At present we have the notation, say 25 horsepower, which means a variety of things. It may mean a small torque and high speed or vice versa.

In the development of mining locomotives it has been determined that the weight of any locomotive running at speed of 6 to 8 miles per hour with intermittent load should be on the basis of 400 lb. for each 1 horsepower of the rating of the motors and also the weight should be eight times the rated draw bar pull regardless of speed.

If the work is continuous, the above weights should be decreased 25%.

A certain part of the power of a locomotive must be used to haul itself and where the grades are heavy this amounts to considerable.

The following table, No. 4, gives the normal draw bar pull on various grades for several different sizes locomotives:

TABLE 4.—DRAWBAR PULLS ON GRADES.

H. P.	Weight.	Grades.						
		Level.	1%.	2%.	3%.	4%.	5%.	6%.
10	4,000	500	460	420	380	340	300	260
20	8,000	1,000	920	840	760	680	600	520
30	12,000	1,500	1,380	1,260	1,140	1,020	900	780
50	20,000	2,500	2,300	2,100	1,900	1,700	1,500	1,300
70	28,000	3,500	3,220	2,940	2,660	2,380	2,100	1,820
100	40,000	5,000	4,600	4,200	3,800	3,400	3,000	2,600

In mines it is found that the friction between wheel and rail is less than outside. This is due principally to the dampness and powdered coal on rail.

It is therefore considered that the running tractive effort with chilled wheels is one-eighth the weight.

The following table, No. 5, gives the hauling capacities of locomotives in tons of 2,000 lb. on various grades.

TABLE 5.—HAULING CAPACITIES OF LOCOMOTIVES ON VARIOUS GRADES, IN TONS OF 2,000 LBS.

H. P.	Weight.	Draw Bar Pull on Level.	Frictional Car Resistance per Ton on Level.	Grades.											
				Level.	1%	1½%	2%	2½%	3%	3½%	4%	5%	6%	7%	8%

The numbers 20, 30 and 40 opposite each size locomotive is the different resistances per ton in cars due to friction.

If a short adverse grade is encountered, the indicated loads may be increased 50%.

When motors are given overloads they heat rapidly and this heating varies directly as the square of the current.

For this reason each motor should have a given ampere

rating for continuous work and from such rating, having the profile, it is possible to calculate the number of trips of given size any locomotive is capable of hauling in a given time.

Thus a motor which has a rating of 40 amperes for regular work if worked for 3 minutes at 100 amperes should not be subjected to such work oftener than $3 \times 100^2 = x \times 40^2$, $x = 18\frac{1}{2}$ min.

In order that this principle may be applied we will use the same problem as the one in which we calculated for air haulage, on page 189, November number of MINES AND MINERALS, which was as follows:

EXAMPLE.—It is desired to haul trips of 60 cars, empties weighing 2,000 lb. and loads 6,000 lb. each, over a track having the following profile, and with one charge of air. All grades are in favor of loads.

PROFILE OF ROAD.

Grade %.	Distance.	Grade %.	Distance.	Grade %.	Distance.
1.3	800 ft.	0.3	700 ft.	2.4	400 ft.
2.0	600 ft.	1.77	1,025 ft.	3.5	425 ft.
1.3	800 ft.	0.9	800 ft.	1.2	820 ft.
